More than 170 proteins are necessary for assembly of ribosomes in eukaryotes. However, cofactors that function with each of these proteins, substrates on which they act, and the precise functions of assembly factors—e.g., recruiting other molecules into preribosomes or triggering structural rearrangements of pre-rRNPs—remain mostly unknown. Here we investigated the recruitment of two ribosomal proteins and 5S ribosomal RNA (rRNA) into nascent ribosomes. We identified a ribonucleoprotein neighborhood in preribosomes that contains two yeast ribosome assembly factors, Rpf2 and Rrs1, two ribosomal proteins, rpL5 and rpL11, and 5S rRNA. Interactions between each of these four proteins have been confirmed by binding assays *in vitro*. These molecules assemble into 90S preribosomal particles containing 35S rRNA precursor (pre-rRNA). Rpf2 and Rrs1 are required for recruiting rpL5, rpL11, and 5S rRNA into preribosomes. In the absence of association of these molecules with pre-rRNPs, processing of 27SB pre-rRNA is blocked. Consequently, the abortive 66S pre-rRNPs are prematurely released from the nucleolus to the nucleoplasm, and cannot be exported to the cytoplasm.

In eukaryotes, 79 ribosomal proteins associate with ribosomal RNA (rRNA) to produce 40S and 60S ribosomal subunits (Woolford and Warner 1991). Three of the four rRNAs in mature ribosomes are derived from the 35S–45S rRNA precursor (pre-rRNA) transcribed by RNA polymerase I, while the fourth rRNA, 5S rRNA, is transcribed from separate genes by RNA polymerase III. The 35S–45S primary transcript is packaged into a 90S ribonucleoprotein particle (RNP), together with a subset of assembly factors and ribosomal proteins. Subsequent steps trigger folding, modification, and processing of pre-rRNAs and association of additional assembly factors and ribosomal proteins in 43S and 66S assembly intermediates. These pre-rRNPs undergo further maturation in the nucleolus, nucleoplasm, and then cytoplasm to form functional 40S and 60S ribosomal subunits, respectively (Fig. 1A; Fatica and Tollervey 2002; Fromont-Racine et al. 2003; Raué 2003; Granneman and Baserga

2004). Preribosomal particles in the assembly pathway are distinguished by the presence of successive pre-rRNA processing intermediates (Fig. 1A). However, it is not clear into which of the consecutive preribosomes 5S rRNA and each ribosomal protein are incorporated, which assembly factors are required to recruit these molecules, or how they do so. Furthermore, the mechanisms by which constituents of nascent ribosomes facilitate folding, processing, and modification of pre-rRNAs remain elusive.

5S rRNA is essential for maturation of preribosomes and for the function of mature ribosomes (Van Ryk et al. 1992; Dechampesme et al. 1999; Kiparisov et al. 2005). Steitz and coworkers defined a pathway of assembly of 5S rRNA into ribosomes in HeLa cells. Newly synthesized 5S pre-rRNA binds transiently to the La protein (Rinke and Steitz 1982; Yoo and Wolin 1994). Following 3'-end maturation, 5S rRNA binds to ribosomal protein rpL5, then assembles into ribosomes (Steitz et al. 1988). In yeast, extraribosomal 5S rRNA was found in a complex with rpL5, indicating that yeast rpL5 also associates with 5S rRNA before incorporation into preribo-

Figure 1. Identification and purification of a subcomplex containing 5S rRNA, ribosomal proteins rpL5 and rpL11, and assembly factors Rpf2 and Rrs1. (A) The pre-rRNP maturation pathway in *Saccharomyces cerevisiae*. The 90S pre-rRNP containing 35S pre-rRNA and a subset of ribosomal proteins and assembly factors is converted into 43S and 66S precursor particles, then to mature 40S and 60S ribosomal subunits. Four consecutive 66S pre-rRNPs contain 27SA₂, 27SA₃, 27SB, and 25.5 plus 7S pre-rRNAs, respectively, plus ribosomal proteins and assembly factors. Ribosome biogenesis begins in the nucleolus and continues in the cytoplasm; final steps occur in the cytoplasm. (B, left) Amounts of Rpf2 or Rrs1 sedimenting as a small complex near the top of gradients increase in the *rrp1-1* mutant compared with wild-type cells. Wild-type yeast (JWY7087 and JWY7461) and temperature-sensitive *rrp1-1* mutant yeast (JWY7089 and JWY7462) expressing TAP-tagged Rpf2 or Rrs1 were grown at 25°C to 1.5×10^7 cells per milliliter and shifted for 5 h to 37°C. Extracts from the wild-type (top) and *rrp1-1* mutant (bottom) strains were fractionated on 7%–47% sucrose gradients, and amounts of Rpf2-TAP or Rrs1-TAP proteins in each fraction were assayed by Western immunoblotting. Fractions containing 43S and 66S preribosomes are indicated. (Right) Amounts of Rpf2 and Rrs1 in whole-cell extracts remain the same in *rrp1-1* mutant compared with wild-type cells. (C) Enrichment of the Rpf2-subcomplex in the *rrp1-1* mutant compared with other preribosomal proteins. Whole-cell extracts from the *RRP1* and *rrp1-1* strains were subjected to TAP using Rpf2-TAP or Rrs1-TAP. Copurifying proteins were resolved by SDS-PAGE and stained with silver. Proteins enriched in mutant strains are labeled. (D) Enrichment of proteins in TAP-purified samples does not retain the *RPF2-TAP* strains JWY7087 or JWY7089 (top), and proteins from whole-cell extracts of the same strains (bottom), were subjected to Western blot analysis. Samples on the left in each pair are from wild-type *RRP1* cells and those on the right are from the *rrp1-1* mutant. Proteins from equal amounts of cells were loaded in each lane. Similar results were obtained with the *RRS1-TAP* strain (data not shown). (E) The purified Rpf2 subcomplex contains Rpf2, Rrs1, rpL5, and rpL11. Fractions 5–7 pooled from the gradients of *rrp1-1* extracts, shown in B, were subjected to TAP purification using either Rpf2-TAP or Rrs1-TAP. Purified proteins were resolved by SDS-PAGE, stained by Coomassie blue, and identified by mass spectrometry. (F) 5S rRNA is present in the purified Rpf2 subcomplex. RNA was extracted from whole-cell extracts (left), affinity-purified samples from untagged strain (middle), and Rpf2 subcomplex purified from gradient fractions 5–7 (right), resolved by polyacrylamide gel electrophoresis, and assayed by Northern blotting using specific oligonucleotide probes. (G) Docking of atomic models of ribosomal proteins and 5S rRNA into a 15 Å resolution cryoelectron microscopy map of yeast 60S ribosomal subunits (Spahn et al. 2001) demonstrates that rpL5 (blue), rpL10 (yellow), rpL11 (red), and 5S rRNA (green) are adjacent to one another in mature 60S ribosomal subunits.

sult from changes in their amounts in whole-cell extracts. TAP-purified samples from the *RPF2-TAP* strains JWY7087 or JWY7089 (top), and proteins from whole-cell extracts of the same strains (bottom), were subjected to Western blot analysis. Samples on the left in each pair are from wild-type *RRP1* cells and those on the right are from the *rrp1-1* mutant. Proteins from equal amounts of cells were loaded in each lane. Similar results were obtained with the *RRS1-TAP* strain (data not shown). (E) The purified Rpf2 subcomplex contains Rpf2, Rrs1, rpL5, and rpL11. Fractions 5–7 pooled from the gradients of *rrp1-1* extracts, shown in B, were subjected to TAP purification using either Rpf2-TAP or Rrs1-TAP. Purified proteins were resolved by SDS-PAGE, stained by Coomassie blue, and identified by mass spectrometry. (F) 5S rRNA is present in the purified Rpf2 subcomplex. RNA was extracted from whole-cell extracts (left), affinity-purified samples from untagged strain (middle), and Rpf2 subcomplex purified from gradient fractions 5–7 (right), resolved by polyacrylamide gel electrophoresis, and assayed by Northern blotting using specific oligonucleotide probes. (G) Docking of atomic models of ribosomal proteins and 5S rRNA into a 15 Å resolution cryoelectron microscopy map of yeast 60S ribosomal subunits (Spahn et al. 2001) demonstrates that rpL5 (blue), rpL10 (yellow), rpL11 (red), and 5S rRNA (green) are adjacent to one another in mature 60S ribosomal subunits.

somes (Deshmukh et al. 1993). In *Xenopus* oocytes, 5S rRNA is synthesized before other constituents of ribosomes and is stored in the cytoplasm for long periods as 7S RNPs that contain transcription factor TFIIIA or as 42S RNPs containing the two thesaurin proteins and tRNAs (Picard and Wegnez 1979; Guddat et al. 1990; Viel

et al. 1991). During vitellogenesis, 5S rRNA is released from these particles, associates with rpL5, and assembles into ribosomes. In bacteria, association of 5S rRNA with ribosomes is dependent on ribosomal proteins L18 (homolog of eukaryotic rpL5), L5 (homolog of eukaryotic rpL11), and L25 (no obvious homolog) (Yu and Wittmann

1973). These three proteins can bind to 5S rRNA independently of ribosomes and can associate in vitro with ribosome assembly intermediates (Gray et al. 1972; Spierer and Zimmermann 1978). However, it has not yet been determined whether the same pathway of assembly of 5S rRNA into bacterial ribosomes occurs in vivo. In HeLa cells, 5S rRNA is first detected in 55S precursors to 60S subunits, but exactly which precursors is unclear (Warner and Soeiro 1967). In yeast, expression of certain unstable mutant forms of yeast 5S rRNA slows processing of 27SB pre-rRNA to mature 25S and 5.8S rRNAs and diminishes production of 60S ribosomal subunits (Van Ryk et al. 1992; Dechampsme et al. 1999). Taken together, these results suggest that 5S rRNA assembles together with rpL5 into preribosomes at an intermediate step in particle maturation, possibly before 27SB pre-rRNA undergoes further processing. However, which assembly factors, if any, recruit 5S rRNA into pre-rRNPs, and into which assembly intermediates 5S rRNA is recruited, remain unknown.

How and when does each ribosomal protein join nascent ribosomes and what roles does each protein play in ribosome synthesis? In bacteria, in vitro reconstitution of ribosomes revealed a hierarchical pathway of assembly of ribosomal proteins with rRNA (Held et al. 1973). Whether this pathway is identical to that in vivo remains to be established. In contrast, there is only a low-resolution map for the pathway of ribosome assembly in eukaryotes. Kinetic labeling studies in yeast identified several ribosomal proteins that assemble into preribosomes at relatively early or late stages (Kruiswijk et al. 1978). Which assembly factors might recruit ribosomal proteins has not been determined, except in a few cases. Yeast ribosome assembly factor Rrb1 physically interacts with r-protein rpL3 and regulates its expression (Iouk et al. 2001), suggesting that Rrb1 might target rpL3 into preribosomes (Schaper et al. 2001). Assembly factor Sgt1 binds to rpL10p (Eisinger et al. 1997), and is thought to facilitate loading of rpL10 into preribosomes in the cytoplasm (West et al. 2005). The participation of each small subunit ribosomal protein in biogenesis of 40S ribosomes, specifically maturation of 18S rRNA and nuclear export of 43S preribosomes, has been systematically examined. All essential ribosomal proteins of the small subunit except rpS7, rpS30, and rpS31 are required for pre-rRNP maturation at different intermediate steps. More interestingly, correlations between the timing of assembly and the timing of function were observed for some of these ribosomal proteins (Ferreira-Cerca et al. 2005), which emphasizes the importance of studying recruitment of ribosomal proteins and their functions in ribosome synthesis. In contrast, functions in ribosome assembly for most large subunit ribosomal proteins remain mostly unexplored except for rpL10, which is necessary for recycling of the export adaptor Nmd3 (West et al. 2005).

Here we identify a ribonucleoprotein neighborhood in preribosomes that contains two assembly factors, Rpf2 and Rrs1, two ribosomal proteins, rpL5 and rpL11, and 5S rRNA. We show that Rpf2 and Rrs1 are necessary for assembly of 5S rRNA, rpL5, and rpL11 into 90S preribo-

somes containing 35S pre-rRNA. In the absence of incorporation of these molecules into nascent ribosomes, preribosomal particles remain largely intact; however, 27SB pre-rRNA cannot efficiently undergo further processing. Consequently, these abortive 66S pre-rRNPs are prematurely released from the nucleolus to the nucleoplasm, and cannot be exported to the cytoplasm. Our characterization of the Rpf2 neighborhood provides novel insights into when and how ribosomal proteins and 5S rRNA are delivered into nascent ribosomes.

Results

A subcomplex in preribosomes that contains ribosome assembly factors Rpf2 and Rrs1, ribosomal proteins rpL5 and rpL11, and 5S rRNA

Previous yeast two-hybrid experiments revealed pairwise interactions between Rpf2, Rrs1, and rpL11 (Miyoshi et al. 2002; Morita et al. 2002). In mature yeast ribosomes, rpL11 is adjacent to 5S rRNA and rpL5 (Fig. 1G; Tsay et al. 1994; Spahn et al. 2001). Thus, it is possible that in ribosome assembly intermediates, 5S rRNA and rpL5 are close neighbors of Rpf2, Rrs1, and rpL11. To determine whether these five molecules form a neighborhood within preribosomal particles, we used a combined genetic and biochemical approach to purify subcomplexes from nascent ribosomes. We took advantage of the phenotype of the *rrp1-1* mutant defective in ribosome biogenesis. When this temperature-sensitive mutant is shifted to the nonpermissive temperature, maturation of 60S ribosomal subunits is blocked, 27S pre-rRNA processing intermediates are degraded, and 66S pre-rRNPs fall apart into subcomplexes (Andrew et al. 1976; Harnpicharnchai et al. 2001; Horsey et al. 2004; Miles et al. 2005). This enables identification of neighborhoods that would normally form within assembling ribosomes, but dissociate from them when preribosomal particles in the *rrp1-1* mutant disassemble upon shifting to nonpermissive temperature. Such subcomplexes would also be evident in the *rrp1-1* mutant if they assembled outside of pre-rRNPs, but were unable to join nascent ribosomes when Rrp1 is inactive.

Two initial results suggested that Rpf2, Rrs1, rpL5, rpL11, and 5S rRNA might be present in a subcomplex within assembling ribosomes: (1) the pattern of sedimentation of the two assembly factors on sucrose gradients (Fig. 1B, left), and (2) enrichment of Rpf2, Rrs1, rpL5, and rpL11 compared with total proteins from 66S pre-rRNPs when either TAP-tagged Rpf2 or Rrs1 was used for affinity purification of complexes from the *rrp1-1* mutant (Fig. 1C). When extracts from wild-type and *rrp1-1* mutant cells were subjected to centrifugation on 7%–47% sucrose gradients, Rpf2 and Rrs1 were evident in two peaks, one in fractions 15–17 containing 66S preribosomes, and the other in fractions 5–7, where smaller macromolecular complexes (~450–700 kDa) sediment (Fig. 1B, left). Relative to extracts from wild-type strains, mutant extracts contained more Rpf2 and Rrs1 in fractions 5–7, and less of each protein in fractions 15–17, suggesting that an extraribosomal subcomplex contain-

ing Rpf2 and Rrs1 is present in larger amounts in the *rrp1-1* mutant strains. Amounts of Rpf2 and Rrs1 in whole-cell extracts remained the same in the *rrp1-1* mutant compared with wild-type cells (Fig. 1B, right).

Affinity purification using Rpf2-TAP or Rrs1-TAP from whole-cell extracts of *RRP1* and *rrp1-1* strains revealed the proteins normally present in purified 66S pre-rRNPs (Fig. 1C). However, silver staining and Western blotting demonstrated that Rpf2, Rrs1, rpL5, rpL11, rpP0, and Ebp2 were enriched among proteins purified from the *rrp1-1* mutant (Fig. 1C,D). These proteins were not enriched when affinity purification was carried out from *rrp1-1* mutant extracts using other TAP-tagged ribosome assembly factors such as Nop7, Ssf1, Nug1, or Nsa3 (Supplementary Fig. 1), indicating that these enriched proteins are specifically associated with Rpf2 and Rrs1. Immunoblot assays showed that equal amounts of each protein were present in whole-cell extracts of wild-type yeast and the *rrp1-1* mutant (Fig. 1D), demonstrating that differential purification did not result simply from the presence of greater amounts of these proteins in the mutant strain. Taken together, these results suggest that Rpf2, Rrs1, rpL5, rpL11, rpP0, and Ebp2 might exist together in a subcomplex.

In order to purify this subcomplex, we fractionated the *rrp1-1* mutant extract on sucrose gradients (Fig. 1B, left), then carried out affinity purification from fractions 5–7 using either TAP-tagged Rpf2 or Rrs1. We recovered Rpf2, Rrs1, rpL5, and rpL11 from these fractions (Fig. 1E). In both cases, greater amounts of Rpf2 and Rrs1 than rpL5 and rpL11 were obtained, suggesting that these fractions might contain a mixture of an Rpf2/Rrs1 heterodimer and the Rpf2/Rrs1/rpL5/rpL11 subcomplex (Rpf2 subcomplex).

RpP0 is located adjacent to 5S rRNA, rpL5, and rpL11 in mature yeast ribosomes (Fig. 1G; Ballesta and Rem-

acha 1996). Ebp2 was shown to interact with Rrs1 by a two-hybrid assay (Miyoshi et al. 2002). Thus, it seemed likely that rpP0 and Ebp2 also might be present in the Rpf2 subcomplex. However, these two proteins were not recovered in the purified subcomplex, perhaps due to dissociation during centrifugation or TAP purification.

The discovery that rpL5 and rpL11, two proteins that are adjacent to 5S rRNA in mature ribosomes (Spahn et al. 2001), are present in the Rpf2 subcomplex suggested that the subcomplex might also contain 5S rRNA. To test RNA components of the Rpf2 subcomplex, RNA was extracted from purified subcomplex and hybridized to a microarray that tiles all known yeast noncoding RNAs. Results showed the presence of 5S rRNA in the Rpf2 subcomplex (data not shown). Northern blotting of RNA extracted from the subcomplex confirmed that it does in fact contain 5S rRNA, but not 5.8S rRNA or 7S pre-rRNA (Fig. 1F).

Interactions between proteins in the Rpf2 subcomplex

In order to map protein–protein interactions within the Rpf2 subcomplex, we performed yeast two-hybrid assays. Pairwise Rpf2–Rrs1, Rpf2–rpL11, and Rrs1–rpL11 interactions *in vivo* were defined, with interactions between Rpf2 and Rrs1 being stronger than for any other pair of proteins (Supplementary Table 1). To test whether these interactions were direct, GST pull-down assays were carried out *in vitro* (Fig. 2A). GST–Rpf2 bound specifically to Rrs1. Likewise, GST–Rrs1 interacted directly with Rpf2, and also with rpL11. GST–rpL11 bound to Rpf2. GST–rpL5 bound to Rpf2 and to rpL11, and less well to Rrs1. When tandem affinity purification (TAP) was carried out with extracts treated with a cocktail of phosphatase inhibitors that disrupts pre-rRNPs (Miles et al. 2005), only Rrs1 copurified with

Figure 2. Direct physical interactions between Rpf2, Rrs1, rpL5, and rpL11. (A) Synthetic [³⁵S]methionine-labeled Rpf2, Rrs1, rpL5, or rpL11 proteins (*) were incubated with GST–Rrs1, Rpf2, rpL5, or rpL11 fusion proteins. (Middle lane) As negative controls, synthetic proteins were incubated with GST beads only. Complexes were eluted from glutathione beads, subjected to SDS-PAGE, and detected by autoradiography. Fifty percent of the input ³⁵S-labeled proteins in each assay (left lane) and 100% of the pull-down (right lane) are shown. (B) Purification of an Rpf2/Rrs1 heterodimer from whole-cell extracts. Whole-cell extract from wild-type strain JWY7087 was subjected to affinity purification using TAP-tagged Rpf2. Prior to TAP purification, half of the extract was incubated with phosphatase inhibitors, which disrupts pre-rRNPs. Purified proteins were resolved by SDS-PAGE, stained with silver, and identified by mass spectrometry. (C) Protein–protein interactions within the Rpf2 subcomplex.

TAP-tagged Rpf2 (Fig. 2B), consistent with the strong interactions between Rpf2 and Rrs1 observed in the two-hybrid and pull-down experiments. These data confirm and extend previous yeast two-hybrid data from Mizuta and coworkers (Miyoshi et al. 2002; Morita et al. 2002; Nariai et al. 2005), leading us to generate a model for protein–protein interactions within the Rpf2 subcomplex (Fig. 2C).

Rpf2 and Rrs1 are required for recruitment of 5S rRNA and ribosomal proteins rpL5 and rpL11 into nascent ribosomes

The presence of 5S rRNA, rpL5, and rpL11 in the Rpf2 subcomplex suggested that assembly factors Rpf2 and Rrs1 might be involved in recruiting these three molecules into preribosomes. Each of the four protein components of the Rpf2 subcomplex is required for production of 60S ribosomal subunits (Moritz et al. 1990; Deshmukh et al. 1993; Morita et al. 2002; Wehner and Baserga 2002). In addition, upon depletion of Rpf2 or Rrs1, processing of 27SB pre-rRNA is delayed, similar to what occurs when levels of 5S rRNA are diminished (Van Ryk et al. 1992; Dechampesme et al. 1999).

To test whether Rpf2 and Rrs1 are necessary for incorporation of 5S rRNA, rpL5, or rpL11 into nascent ribo-

somes, we first assayed the interdependence of these four proteins for assembly into pre-rRNPs. To do so, we affinity-purified preribosomes from strains in which each of the four proteins was individually depleted, using repressible *GAL1* promoter fusions of *RPF2*, *RRS1*, *RPL5*, or *RPL11*. These strains also contained *NOP7-TAP* to enable purification of 90S pre-rRNPs as well as each of the four consecutive 66S pre-rRNPs (Harnpicharnchai et al. 2001). Upon shifting each strain from galactose- to glucose-containing medium, expression of *GAL1* promoter constructs was turned off and amounts of each protein subsequently decreased (Supplementary Fig. 2A; Moritz et al. 1990; Deshmukh et al. 1993). Growth of these four strains expressing *GAL1* promoter-regulated proteins severely slowed 8–10 h after transfer to glucose, and levels of 60S ribosomal subunits specifically decreased (Supplementary Fig. 2B,C; Moritz et al. 1990; Deshmukh et al. 1993).

SDS-PAGE and Western immunoblot analysis of proteins from preribosomal particles purified from each of the four depleted strains demonstrated that pre-rRNPs were largely intact. Most of the preribosomal proteins were recovered in amounts similar to those from unshifted strains (Fig. 3A). Strikingly, amounts of Rpf2, Rrs1, rpL5, and rpL11 were substantially decreased relative to levels of other protein constituents of pre-rRNPs

Figure 3. 5S rRNA, rpL5, and rpL11 are not recruited into 66S preribosomes in the absence of Rpf2 or Rrs1. Yeast strains *GAL-RPF2* (JWY8129), *GAL-RRS1* (JWY8132), *GAL-RPL5* (JWY8108), and *GAL-RPL11* (JWY8112) were grown at 30°C in galactose medium to 3×10^7 cells per milliliter. A second culture of each strain was grown in galactose medium and shifted to glucose medium for 16 h to 3×10^7 cells per milliliter to deplete the respective proteins. Whole-cell extracts were subjected to TAP purification, using Nop7-TAP to isolate preribosomes. (A) Proteins present in the affinity-purified preribosomes were resolved by SDS-PAGE and stained with silver (left), or subjected to Western blot analysis (right). In each sample pair, proteins from cells grown in galactose-containing medium are on the left and those from cells transferred to glucose are on the right. (B) RNA was extracted from each of the TAP-purified samples described above, as well as from wild-type cells (JWY6938), resolved by denaturing gel electrophoresis, and assayed for 5S rRNA or 27SB pre-rRNA by Northern blotting or primer extension.

in the four depleted strains. In contrast, when any of 11 other assembly factors was depleted, levels of Rpf2, Rrs1, rpL5, and rpL11 present in preribosomes did not change (data not shown).

Northern blotting demonstrated that amounts of 5S rRNA present in 66S pre-rRNPs purified from each of the four depleted strains were approximately sevenfold to 12-fold lower relative to the undepleted strains (Fig. 3B). Amounts of 5S rRNA in preribosomes purified from wild-type cells grown in galactose-containing medium or shifted from galactose- to glucose-containing medium were identical, indicating that levels of 5S rRNA in preribosomes are not sensitive to these carbon source changes (Fig. 3B). Consistent with the delay in 27SB pre-rRNA processing previously observed for Rpf2- and Rrs1-depleted strains, preribosomes isolated from the four depleted strains were enriched for those bearing 27SB pre-rRNA (Fig. 3B). That only modestly larger amounts of 27SB pre-rRNA were recovered may reflect an incomplete block in pre-rRNA processing, together with some turnover of abortive assembly intermediates. Taken together, these results reveal that each of the four proteins in the subcomplex, Rpf2, Rrs1, rpL5, and rpL11, is necessary to recruit all components of the subcomplex, including 5S rRNA, into preribosomal particles.

Interestingly, we also observed a measurable decrease in the amounts of Nog2 and rpL10 present in preribosomes purified from the depleted strains (Fig. 3A). The absence of these two proteins could account in part for the phenotypes observed upon failure to assemble the Rpf2 subcomplex into preribosomes, namely, defects in processing of 27SB pre-rRNA and export of preribosomes from the nucleus (see Discussion).

We independently assayed pre-rRNPs in the Rpf2- and Rrs1-depleted strains using TAP-tagged Ssf1. This assembly factor enters the pathway early, in 90S pre-rRNPs, dissociates from 66S particles containing 27SB pre-rRNA, and is not present in late 66S pre-rRNPs containing 25.5S plus 7S pre-rRNAs (Fatica et al. 2002). Rpf2, Rrs1, rpL5, rpL11, and rpL10 were present in preribosomes purified from wild-type cells using Ssf1-TAP, but were present in much lower amounts when Rpf2 or Rrs1 were depleted (Supplementary Fig. 3). These results confirm our findings with Nop7-TAP, and more importantly, demonstrate that components of the Rpf2 subcomplex associate with preribosomes before Ssf1 dissociates from the pre-rRNPs containing 27SB pre-rRNA.

Fate of components of the Rpf2 subcomplex when they cannot assemble into preribosomes

What happens to constituents of the Rpf2 subcomplex when they are unable to assemble into preribosomes? Western blotting of whole-cell extracts revealed that both Rpf2 and Rrs1 decreased four- to sevenfold after depletion of any of the other three subcomplex proteins (Fig. 4). Levels of Rrs1 or Rpf2 in cells did not decrease when ribosome assembly was blocked by other means; e.g., in *rrp1-1* or *nop4-3* mutants (data not shown). While Nog2 was absent from preribosomes upon depletion of each protein in the Rpf2 subcomplex, levels of it remained the same in whole-cell extracts from the mutants compared with wild-type cells (Fig. 4). Thus, when constituents of the Rpf2 subcomplex cannot associate properly with each other and assemble into preribosomes, Rpf2 and Rrs1 are specifically turned over (Fig. 7, below). In contrast, levels of rpL5 or rpL11 only decreased 1.5-fold to twofold in the four depleted strains (Fig. 4). This smaller decrease in cellular levels of these two ribosomal proteins may simply reflect the fact that the majority of rpL5 and rpL11 present before initiating the depletions is in mature 60S ribosomal subunits and thus is unlikely to turn over upon blocking production of new 60S ribosomes. In the absence of synthesis of new ribosomes, the total number of ribosomes per cell is diminished by dilution upon cell division, which can account in part for the observed decrease in the amounts of rpL5 and rpL11. This is evident from the decreased amounts of rpL1, rpL3, and rpL8 in whole-cell extracts from the depleted strains (Fig. 4). Nevertheless, a small portion of rpL5 and rpL11 synthesized after depletion of any one of the Rpf2 subcomplex proteins may be unstable. Turnover of unassembled Rpf2 and Rrs1 (Fig. 7, below) may serve as signals to ensure that when 5S rRNA, rpL5, and rpL11, three components of mature ribosomes, cannot assemble into preribosomes, biogenesis of 60S subunits does not proceed.

Nuclear export of preribosomes is blocked upon depletion of Rpf2, Rrs1, or rpL5

Export of preribosomes to the cytoplasm is perturbed in yeast strains expressing lower than wild-type amounts of 5S rRNA, suggesting that proper delivery of 5S rRNA to pre-rRNPs is necessary to produce particles competent for nuclear export (Dechampsme et al. 1999). Thus we

Figure 4. Rpf2 and Rrs1 are unstable upon depletion of each of the Rpf2 subcomplex proteins. Yeast strains *GAL-RPF2* (JWY8129), *GAL-RRS1* (JWY8114 or JWY8132), *GAL-RPL5* (JWY8108 or JWY8109), and *GAL-RPL11* (JWY8080 or JWY8112) were grown at 30°C in galactose-containing medium and shifted to glucose medium for 17 h to 3×10^7 cells per milliliter. Proteins in whole-cell extracts were assayed by Western blotting. Samples on the left for each pair are from cells grown in galactose medium and those on the right are from cells grown in galactose medium and shifted to glucose medium.

tose-containing medium to 3×10^7 cells per milliliter. A second culture of each grown in galactose medium for 17 h to 3×10^7 cells per milliliter. Proteins in whole-cell extracts were assayed by Western blotting. Samples on the left for each pair are from cells grown in galactose medium and those on the right are from cells grown in galactose medium and shifted to glucose medium.

predicted that depletion of any protein in the Rpf2 subcomplex would block transport of nascent ribosomes from the nucleus to the cytoplasm. To test this idea, we expressed eGFP-tagged rpL25, a reporter for 66S pre-rRNP export (Hurt et al. 1999), in strains containing *GAL1*-promoter fusions of *RPF2*, *RRS1*, or *RPL5*. When these strains were shifted from galactose- to glucose-containing medium, eGFP-rpL25 localized primarily in the nucleus (Fig. 5). In contrast, eGFP-rpL25 was located predominantly in the cytoplasm in cells grown in galactose (Figs. 5, 7, below). Previously, Miyoshi et al. (2004) found that nuclear export of preribosomes is blocked in temperature-sensitive *rrs1* mutants. This export defect can be explained by our finding that, similar to the depletion strains, preribosomes purified from the *rrs1-84* and *rrs1-124* mutants lack Rpf2, Rrs1, rpL5, and rpL11 (Supplementary Fig. 4).

Each member of the Rpf2 subcomplex assembles into 90S preribosomes

Identification of pre-rRNAs that copurify with assembly factors enables one to determine with which of the consecutive assembly intermediates the protein is associated, and thus when each protein assembles into and exits from preribosomes (Harnpicharnchai et al. 2001; Fatica et al. 2002; Saveanu et al. 2003; Miles et al. 2005). To determine when Rpf2 and Rrs1 assemble into pre-rRNPs, we assayed pre-rRNAs that copurify with Rpf2-TAP or Rrs1-TAP. Primer extension results indicated that 35S, 27SA₂, and 27SB pre-rRNAs associate with Rpf2 as well as Rrs1 (Fig. 6A), demonstrating that both

Rpf2 and Rrs1 assemble into 90S pre-rRNPs containing 35S pre-rRNA.

Another way to assay whether assembly factors associate with similar preribosomal particles is to identify the proteins that copurify with those assembly factors. Forty-five different ribosome assembly factors copurify with TAP-tagged Rpf2 or Rrs1 from wild-type cells. All but seven of these proteins were found in both Rpf2 and Rrs1-containing complexes (Supplementary Table 2), indicating that Rpf2 and Rrs1 are present in similar assembly intermediates.

To determine when rpL5 and rpL11 are incorporated into preribosomes, we carried out a different set of experiments. Because mature 60S ribosomal subunits are present in great excess compared with preribosomes (>100-fold), it is difficult to specifically assay preribosomal RNAs directly coimmunoprecipitating with ribosomal proteins from whole-cell extracts. To overcome this problem, we first purified 90S and 66S preribosomes away from mature ribosomes using TAP-tagged assembly factor Nop7 (Fig. 6B; Harnpicharnchai et al. 2001). We then assayed with which of these purified pre-rRNPs HA-tagged rpL5 or rpL11 is associated by coimmunoprecipitation using anti-HA antiserum. As observed for Rpf2 and Rrs1, 35S, 27SA₂, 27SA₃, and 27SB, pre-rRNAs coprecipitated with both rpL5-HA3 and rpL11-HA3 (Fig. 6B). Consistent with rpL5 and rpL11 being in early pre-rRNPs, we could detect these two proteins in particles purified using protein A-tagged early assembly factor Rrp5 (data not shown). Rrp5 is present in 90S preribosomes containing 35S pre-rRNA as well as 66S particles bearing 27SA₂ pre-rRNA (de Boer et al. 2006).

Figure 5. Depletion of Rpf2, Rrs1, or rpL5 causes 66S preribosomes to accumulate in the nucleus. *GAL-RPF2* (JWY7703), *GAL-RRS1* (JWY7706), or *GAL-RPL5* (JWY7696) strains expressing eGFP-tagged rpL25 were grown at 30°C in galactose medium to 3×10^7 cells per milliliter. A second culture of each strain grown in galactose medium was shifted to glucose medium for 17 h to 3×10^7 cells per milliliter. Nuclei were stained with DAPI, and ribosomes containing eGFP-rpL25 were detected by fluorescence microscopy.

Figure 6. Each component of the Rpf2 subcomplex assembles into 90S preribosomes. (A) Whole-cell extracts were prepared from an untagged strain (JY6147) and Rpf2-TAP (JY7087) and Rrs1-TAP (JY7461) strains. RNA was extracted from whole-cell extracts (*left*) and affinity-purified samples (*right*). Five micrograms of total RNA and 100% of purified RNA were used to assay 35S, 27SA₂, and 27SB pre-rRNAs by primer extension. Amounts of 27SA₃ pre-rRNA were very low and thus are invisible in some lanes. No pre-rRNAs copurified upon mock purification from untagged strains. Note that different oligos were used in reactions for 35S and 27S pre-rRNAs, and longer exposure was done for 35S pre-rRNA. (B) Preribosomes were affinity-purified using TAP-tagged Nop7. Purified pre-rRNPs containing rpl5-HA3 or rpl11 were immunoprecipitated by anti-HA antiserum. Five micrograms of total RNA (*left*) and 100% of purified RNA (*right*) were assayed for 35S, 27SA₂, 27SA₃, and 27SB pre-rRNAs by primer extension. Pre-rRNPs from an untagged strain were used as a negative control.

Previously it was observed that rpl5 binds to 5S rRNA soon after it is synthesized and accompanies 5S rRNA into ribosomes (Steitz et al. 1988). Yeast 5S rRNA was found in an extraribosomal complex with rpl5, indicating that yeast rpl5 also associates with 5S rRNA before incorporation into preribosomes (Deshmukh et al. 1993). Taken together, these results establish that Rpf2, Rrs1, rpl5, rpl11, and 5S rRNA assemble into 90S preribosomes containing 35S pre-rRNA (Fig. 7). Intriguingly, this point of entry is well before the first detectable requirement of these molecules for ribosome biogenesis, namely, processing of 27SB pre-rRNA (see Discussion).

More detailed characterization of preribosomes containing Rpf2

Recent technological advances have made it possible to affinity purify preribosomal complexes more rapidly by using a single-step isolation method (Oeffinger et al. 2007); this method allows us to capture transiently interacting components, giving us a more comprehensive picture of preribosomal particle composition. In order to better define Rpf2-containing preribosomes, we applied the single-step purification method to protein A-tagged Rpf2. Copurifying proteins were resolved by SDS-PAGE, visualized by Coomassie staining, and gels were sliced into 1-mm sections. MS and MS/MS were used to identify proteins in each slice (Krutchinsky et al. 2001). Using this approach, we identified 51 different ribosome assembly factors copurifying with Rpf2-ProtA compared with 43 factors using TAP-tagged Rpf2 (Supplementary

Table 2). These additional proteins included several early and late 60S components that are most likely to be present in lower amounts than most other assembly factors in the total population of Rpf2-associated 90S and 66S pre-rRNPs. Moreover, we were able to coisolate the exonucleases Rat1 and Xrn1—as well as the cofactor for Rat1, Rail—with preribosomes for the first time, by affinity purification, which had not been possible using TAP (Johnson 1997; Xue et al. 2000).

Discussion

Purifying and characterizing neighborhoods of molecules within assembling ribosomes have enabled us to investigate in more detail the structure of assembling ribosomes, the functions of ribosome assembly factors, and the pathway of ribosome assembly. We identified and purified a ribonucleoprotein complex containing yeast ribosome assembly factors Rpf2 and Rrs1, ribosomal proteins rpl5 and rpl11, and 5S rRNA. Components of this subcomplex join pre-rRNPs at an early step in the assembly pathway, forming a stable neighborhood within 90S preribosomes. However, the functions in ribosome biogenesis of molecules in this neighborhood are only evident at later maturation steps, processing of 27SB pre-rRNA and proper release of pre-rRNPs from the nucleolus. Upon depletion of each of these four proteins, the other three proteins and 5S rRNA fail to be recruited into pre-rRNPs. Preribosomes lacking the constituents of the Rpf2 neighborhood are largely intact, but they cannot undergo further maturation, are prematurely released

Figure 7. Model for recruitment and function of 5S rRNA, Rpl5, and Rpl11. (*Top*) In wild-type cells, Rpf2 and Rrs1 help to recruit rpl5, rpl11, and 5S rRNA into 90S preribosomal particles containing 35S pre-rRNA. (*Bottom*) When components of the subcomplex cannot assemble into 90S particles, 35S, 27SA₂, 27SA₃ pre-rRNAs can be processed efficiently. However, processing of 27SB pre-rRNA is blocked. The abortive pre-rRNPs are released from the nucleolus to the nucleoplasm, and cannot be exported to the cytoplasm. When the subcomplex cannot be assembled, Rpf2 and Rrs1 are unstable.

from the nucleolus to the nucleoplasm, and cannot be exported to the cytoplasm.

Discovering neighborhoods in assembling ribosomes

Discovery of the Rpf2 subcomplex (Fig. 1) and characterization of direct interactions among the protein components (Fig. 2) support and extend previous observations: (1) Yeast rpl5 and rpl11 and their bacterial homologs L18 and L5 are adjacent to 5S rRNA in the central protuberance of mature 60S (or 50S) ribosomal subunits (Tsay et al. 1994; Spahn et al. 2001; Klein et al. 2004), and (2) two-hybrid assays identified pairwise interactions among Rpf2, Rrs1, rpl5, and rpl11 (Miyoshi et al. 2002; Morita et al. 2002; Nariai et al. 2005).

It is becoming evident that assembly factors, in some cases together with RNA molecules, may form small complexes either prior to entering preribosomal particles or within nascent ribosomes (Harnpicharnchai et al. 2001; Dosil and Bustelo 2004; Krogan et al. 2004; Nissan et al. 2004; Miles et al. 2005; Lebreton et al. 2006; Rosado et al. 2007). Some of these neighborhoods are evident in wild-type cells. However, others are not, perhaps because they only assemble and exist within preribosomes. Alternatively, those that do form before entering pre-rRNPs may very quickly assemble into nascent ribosomes, such that amounts of free subcomplexes are not readily detectable in extracts from wild-type cells.

In order to identify neighborhoods that are not evident

in large amounts in wild-type cells, such as the Rpf2 subcomplex, we used the *rrp1-1* mutant, in which biogenesis of 60S ribosomal subunits is blocked and abortive 66S assembly intermediates fall apart into subcomplexes (Harnpicharnchai et al. 2001; Horsey et al. 2004; Miles et al. 2005). Dissociation of 66S pre-rRNPs into smaller particles may result in part from degradation of the 27S pre-rRNAs within them, mediated by a nuclear surveillance and degradation pathway; e.g., the TRAMP complex and the exosome (Dez et al. 2006). Occasional errors in ribosome assembly in wild-type cells, also resulting in degradation of some preribosomes (Allmang et al. 2000; Kuai et al. 2004), could account for the small amount of Rpf2 and Rrs1 in wild-type extracts that sediments as an ~450- to 700-kDa complex (Fig. 1B). The Rpf2 subcomplex assembles into 90S particles, which is upstream of the block in processing of 27SA₃ pre-rRNA in the *rrp1-1* mutant. Therefore, we believe that most, if not all, of the Rpf2 subcomplex that we purified from the *rrp1-1* mutant had already assembled into preribosomes but dissociated from the abortive 66S A₃ particles. The pattern of physical and functional interactions and the mutual interdependence among Rpf2, Rrs1, rpl5, rpl11, and 5S rRNA convince us that the Rpf2 subcomplex is a specific ribosome assembly intermediate rather than an artifact of the *rrp1-1* mutant. A combination of different approaches (Harnpicharnchai et al. 2001; Dosil and Bustelo 2004; Krogan et al. 2004; Nissan et al. 2004; Miles et al. 2005; Lebreton et al. 2006; this study) should facili-

tate identification of additional neighborhoods, enabling better characterization of physical and functional interactions between preribosomal molecules, and eventually helping define the global structure of consecutive preribosomal particles.

The Rpf2 subcomplex functions in intermediate stages of 66S preribosome maturation and is necessary to recruit assembly factor Nog2 and ribosomal protein rpL10

Processing of 27SB pre-rRNA and subsequent nuclear export of preribosomes are thought to involve complex rearrangements of higher-order structures of pre-rRNAs and pre-rRNPs (Côté et al. 2002), and thus may require the concerted action of a number of assembly factors and ribosomal proteins. Our results indicate that incorporation of 5S rRNA, rpL5, and rpL11 into preribosomes, mediated by Rpf2 and Rrs1, may help trigger these late steps in maturation of 66S pre-rRNPs (Fig. 7). Previously, it was found that depletion or inactivation of 5S rRNA, Rpf2, or Rrs1 delays processing of 27SB pre-rRNA and blocks nuclear export of 66S particles (Dechampesme et al. 1999; Morita et al. 2002; Wehner and Baserga 2002; Miyoshi et al. 2004). Recently, Yao et al. (2007) found that Mex67 and Mtr2 are necessary for nuclear export of 66S preribosomes and bind to 5S rRNA. Our work explains these phenotypes and ties them together by showing that Rpf2, Rrs1, rpL5, and rpL11 are present together in the Rpf2 subcomplex, and are necessary for recruiting each other, as well as 5S rRNA, into nascent ribosomes (Figs. 3, 7).

Upon depletion of the Rpf2 subcomplex proteins, assembly factor Nog2 is absent from preribosomes. Nog2 is a putative GTPase required for processing of 27SB pre-rRNA (Saveanu et al. 2001). Thus, the defect in 27SB pre-rRNA processing observed upon depletion of each of the Rpf2 subcomplex proteins may be partially due to the absence of Nog2 (Fig. 7). As a GTPase, Nog2 may rearrange 66S pre-rRNP structure to create the proper conformation required for further maturation steps, including processing of the spacer sequence ITS2 and nuclear export of preribosomes.

We also found that depletion of Rpf2 subcomplex proteins prevents stable association of rpL10 with preribosomes (Fig. 3A). RpL10 is required for nuclear export of nascent 60S subunits (Gadal et al. 2001). Thus, the observed defects in nuclear export when the Rpf2 subcomplex does not assemble into preribosomes may result in part from the absence of rpL10 from pre-rRNPs. Although previous results suggested that rpL10 does not associate with pre-rRNPs until they reach the cytoplasm (West et al. 2005), we found rpL10 present in early preribosomal particles. As shown in Supplementary Figure 3, when early assembly factor Ssf1 was TAP-tagged to purify preribosomes, rpL10 was identified in pre-rRNPs purified from wild-type cells. However, rpL10 was present in much lower amounts in Ssf1-containing particles when Rpf2 or Rrs1 was depleted. To reconcile these discrepancies, we propose that, analogous to acidic ribo-

somal protein interactions with ribosomes, rpL10 cycles on and off preribosomes (Zinker and Warner 1976; Ballasta and Remacha 1996). Since rpL5, 5S rRNA, and rpL11 lie adjacent to rpL10 in mature ribosomes (Fig. 1G), their absence from pre-rRNPs may create local distortions in the particles, which might prevent rpL10 from assembling into early pre-rRNPs or rejoining later pre-rRNPs. Consistent with this hypothesis, we found that preribosomal particles are intact upon depletion of rpL10 (data not shown), indicating that the absence of rpL10 from pre-rRNPs can be tolerated.

5S rRNA, rpL5, and rpL11 assemble into nascent ribosomes at an early step

To understand the functions of assembly factors and ribosomal proteins, it is useful to determine when each assembly factor and ribosomal protein assembles into preribosomes. Based on the results that the consecutive pre-rRNA processing intermediates 35S, 27SA₂, 27SA₃, and 27SB pre-rRNAs copurify with each of the four proteins in the Rpf2 subcomplex (Fig. 6), we believe that each component of the neighborhood assembles into 90S preribosomes containing 35S pre-rRNA (Fig. 7). That different amounts of 35S pre-rRNA copurify with each of the four proteins might reflect at least two possible assembly mechanisms: (1) Rpf2, Rrs1, rpL5/5S rRNA, and rpL11 might assemble into 90S particles at distinct consecutive substeps. Thus, these five molecules might form a stable neighborhood only after their incorporation into nascent ribosomes. (2) Alternatively, the complete Rpf2 subcomplex might form before joining 90S particles. Using different epitope tags or purification approaches may cause different amounts of pre-rRNAs to copurify with each protein component of the subcomplex. Although these technical limitations prevent us from distinguishing whether components of the Rpf2 subcomplex enter 90S particles before or after assembling with each other, our coimmunoprecipitation experiments do indicate when rpL5/5S rRNA and rpL11 assemble into preribosomes and provide a general approach to accurately map entry points of ribosomal proteins.

Rpf2 contains an RNA-binding motif essential for its function (Wehner and Baserga 2002), and thus may play a key role in targeting 5S rRNA, rpL5, and rpL11 into 90S pre-rRNPs. GST pull-down data in Figure 2A show direct interactions between Rpf2 and rpL5 or rpL11. In archaeobacteria, 5S rRNA is anchored in ribosomes by contacts with five ribosomal proteins and by direct interactions with 23S rRNA (Klein et al. 2004). Thus, stable insertion of 5S rRNA into yeast pre-rRNPs may require establishment of one or more sequential protein–RNA and RNA–RNA interactions. Rpf2 might target rpL5/5S rRNA and rpL11 into 90S particles through interactions with 5S rRNA or 35S pre-rRNA, as well as through protein–protein interactions.

Rpf2, Rrs1, rpL5, rpL11, and 5S rRNA assemble into the 90S particle, but are only necessary for a later step in the assembly pathway, processing of 27SB pre-rRNA.

Thus, in the absence of the Rpf2 subcomplex, preribosomes can still proceed through several early maturation steps to efficiently process 35S, 27SA2, and 27SA3 pre-rRNAs (Fig. 7). The apparent lack of dependence on the Rpf2 subcomplex of these early steps in ribosome maturation might be explained as follows. Components of the subcomplex may function as scaffolding molecules to recruit ribosomal proteins or other assembly factors that only function later, such as Nog2. Alternatively, the Rpf2 subcomplex molecules may help establish and maintain local RNP architecture required in later steps in subunit biogenesis. Such a local distortion caused by the absence of the Rpf2 subcomplex would not be evident by our current assays.

Materials and methods

Yeast strains (Supplementary Table 3) were grown and harvested as described in Horsey et al. (2004). 3HA- and TAP-tagged genes and *GAL1* promoter fusions were generated as described in Longtine et al. (1998) and Harnpicharnchai et al. (2001). Sequences of oligonucleotides used for PCR to tag genes are available on request.

Subcomplexes, preribosomes, ribosomes, and polyribosomes were resolved on 7%–47% sucrose gradients as described in Harnpicharnchai et al. (2001). TAPs of preribosomes or subcomplexes from whole-cell extracts or subcellular fractions were carried out by the methods of Miles et al. (2005). One-step purification of preribosomes from whole-cell extracts was performed as described (Oeffinger et al. 2007). RNAs from whole-cell extracts or enriched by TAP purification were assayed by Northern analysis or primer extension (Horsey et al. 2004). Proteins present in whole-cell extracts, sucrose gradient fractions, purified preribosomes, or assembly subcomplexes were assayed by Western blot analysis (Ausubel et al. 1994). TAP-tagged proteins were detected using alkaline phosphatase conjugated to IgG (Pierce). 3HA-tagged proteins were identified with mouse monoclonal antibody 12CA5. Rabbit polyclonal or mouse monoclonal antibodies were used against ribosomal or nonribosomal proteins.

Proteins copurifying with TAP-tagged Rpf2 or Rrs1 or protein A-tagged Rpf2 were identified by mass spectrometry as described in Eng et al. (1994), Horsey et al. (2004), Guo et al. (2005), and Krutchinsky et al. (2001).

Two-hybrid and GST pull-down assays of protein–protein interactions were performed as described in Miles et al. (2005). Release of preribosomes from nucleoli and export from the nucleoplasm to the cytoplasm were assayed using the rpL25-eGFP reporter system, as described in Hurt et al. (1999), using a Zeiss Axioskop 2 plus microscope.

Acknowledgments

We thank Keiko Mizuta (Hiroshima University) for generously providing strains KM129 and KM403. We thank Mike Snyder (Yale University) for yeast strains expressing GST fusion proteins, Cosmin Saveanu for *GST-RPL5*, and Stan Fields and Tony Hazbun (University of Washington) for two-hybrid plasmids. We are grateful to the following people for generously providing antibodies: John Aris (Nop2), Juan Pedro Ballesta (rpP0), Jesus de la Cruz and Patrick Linder (Has1), David Goldfarb (Nip7), Janine Maddock and Jennifer Fuentes (Nog1), Michael McAlear (Ebp2), Cosmin Saveanu (rpL24, Nog2), Maurice Swanson (rpL39), Bernard Trumpower (rpL10), Arlen Johnson (rpL8), Jon Warner (rpL3), Francois Lacroute (rpL1), Elisabeth Tosta (Cic1), Sandra

Wolin (Lhp1), and Jeff Brodsky (Sec61). We thank Susan Dowd, Mark Bier, Karen Wei, Jeffrey DeGrasse, and Brian Chait for assistance with mass spectrometry. We thank Jonathan Dinman, Arlen Johnson, and Jon Warner, as well as members of our laboratory, for fruitful discussions and for comments on the manuscript. We thank Brooke McCartney for use of her microscope. This work was supported by NIH grant GM28301 to J.L.W., NHLBI grant N01-HV-28180 to Y.G., funds from the government of Thailand to P.H., NIH grant NCRR 5 U54 RR022220 to M.O. and M.P.R., a CIHR fellowship to S.H., and a grant from CIHR to T.R.H. (MOP-49451).
