Heterochromatin protein 1 (HP1) proteins are conserved in eukaryotes, with most species containing several isoforms. Based on the properties of *Drosophila* HP1a, it was proposed that HP1s bind H3K9me_{2,3} and recruit factors involved in heterochromatin assembly and silencing. Yet, it is unclear whether this general picture applies to all HP1 isoforms and functional contexts. Here, we report that *Drosophila* HP1c regulates gene expression, as (1) it localizes to active chromatin domains, where it extensively colocalizes with the poised form of RNA polymerase II (RNAPol II), Pol Ilo^{ser5}, and H3K4me₃, suggesting a contribution to transcriptional regulation; (2) its targeting to a reporter gene does not induce silencing but, on the contrary, increases its expression, and (3) it interacts with the zinc-finger proteins WOC (without children) and Relative-of-WOC (ROW), which are putative transcription factors. Here, we also show that, although HP1c efficiently binds H3K9me_{2,3} in vitro, its binding to chromatin strictly depends on both WOC and ROW. Moreover, expression profiling indicates that HP1c, WOC, and ROW regulate a common gene expression program that, in part, is executed in the context of the nervous system. From this study, which unveils the essential contribution of DNA-binding proteins to HP1c functionality and recruitment, HP1 proteins emerge as an increasingly diverse family of chromatin regulators.

The contribution of chromatin to the regulation of genomic functions is well established. Most frequently, regulation by chromatin involves the establishment of specific patterns of post-translational histone modifications, which result in recruitment of regulatory nonhistone proteins (Ruthenburg et al. 2007). Heterochromatin protein 1 (HP1) constitutes one of the best-studied examples (Hiragami and Festenstein 2005; Hediger and Gasser 2006; Lomberg et al. 2006), where a regulatory nonhistone protein is recruited to chromatin through the recognition of a specific histone modification, di- or trimethylation of Lys 9 on the histone H3 tail (H3K9me_{2,3}). This interaction, which involves the N-terminal chromodomain of HP1, is known to play a fundamental role in the formation and maintenance of heterochromatic domains.

Except in budding yeast, HP1 is widely conserved in eukaryotes, with most species containing several isoforms (Hiragami and Festenstein 2005; Lomberg et al. 2006). HP1 proteins are characterized by a common structural organization consisting of two conserved domains, the N-terminal chromodomain and the C-terminal chromo-shadow domain, which are spaced by a variable nonconserved hinge domain. The existence of multiple isoforms suggests functional specialization, with different isoforms playing different functions. For instance, in *Drosophila*, three of the five HP1 isoforms (HP1a, HP1b, and HP1c) are ubiquitously expressed, while the other two (HP1d/Rhino and HP1e) are predominantly expressed in the germline (Vermaak et al. 2005). Moreover, ubiquitously expressed HP1 isoforms show differential chromosomal distributions, as HP1a is mainly associated to heterochromatin, while HP1c is excluded from centromeric heterochromatin and HP1b is found both at euchromatic and heterochromatic domains (Smothers and Henikoff 2001). A similar situation is observed in mammals, where the patterns of localiza-

Article is online at <http://www.genesdev.org/cgi/doi/10.1101/gad.481408>.

tion of the three HP1 isoforms (HP1 α , HP1 β , and HP1 γ) overlap only partially and show differential dynamics during differentiation and cell cycle progression (Minc et al. 1999; Hayakawa et al. 2003; Dialynas et al. 2007). On the other hand, in the nematode *Caenorhabditis elegans*, two HP1 isoforms exist (HPL1 and HPL2), showing preferential euchromatic association, partially nonoverlapping expression and localization patterns, and distinct mutant phenotypes (Coustham et al. 2006; Schott et al. 2006). Interestingly, the only HP1 protein (TLF2/LHP1) of *Arabidopsis thaliana* appears to localize exclusively to euchromatin, where it colocalizes with H3K27me3 (Nakahigashi et al. 2005).

The molecular mechanisms that determine the differential distribution of the various HP1 isoforms, and their differential functional properties, remain largely unknown. Most of our knowledge about the mechanisms of action of HP1 proteins derives from studies addressing the functional properties of *Drosophila* HP1a or mammalian HP1 α . From these studies, a general picture emerges by which, through the chromodomain, HP1 proteins bind chromatin regions enriched in H3K9me_{2,3} while, through the chromo-shadow domain, recruiting different factors resulting in various functional outcomes; namely, heterochromatin assembly and gene silencing (Hiragami and Festenstein 2005; Hediger and Gasser 2006; Lomberg et al. 2006). It is uncertain whether this general picture applies to all HP1 proteins and possible scenarios. Actually, *Drosophila* HP1a is known to play a more complex role(s) in the regulation of gene expression, as it is required for the expression of several heterochromatic genes (Hearn et al. 1991; Clegg et al. 1998; Lu et al. 2000), and certain euchromatic genes (Cryderman et al. 2005; De Lucia et al. 2005). Moreover, *Drosophila* HP1a is recruited to developmentally regulated genes and heat-shock-induced puffs in an RNA-dependent manner (Piacentini et al. 2003), and in an erythroid cell line, murine HP1 γ was found associated to actively transcribed genes (Vakoc et al. 2005).

In this study, we report on the functional characterization of HP1c, a *Drosophila* HP1 protein of largely unknown properties. Our results show that HP1c extensively colocalizes with poised RNA polymerase II (RNAPol II) and H3K4me₃, a modification that correlates with active chromatin domains (Bernstein et al. 2005; Barski et al. 2007; Heintzman et al. 2007). Moreover, targeting HP1c to a reporter construct does not induce silencing but, on the contrary, results in increased expression of the reporter gene. Here, we also report on the interaction of HP1c with the zinc-finger proteins WOC (without children) (Wismar et al. 2000; Warren et al. 2001), and Relative-of-WOC (ROW), which are putative transcription factors. HP1c efficiently binds H3K9me_{2,3} in vitro, but its binding to chromatin strictly depends on both WOC and ROW. Moreover, expression profiling indicates that HP1c, WOC, and ROW extensively cooperate to regulate gene expression, especially in the context of the nervous system. These results unveil the essential contribution of sequence-specific

DNA-binding proteins to functionality of HP1c and its recruitment to chromatin.

Results

HP1c localizes to active chromatin domains

HP1c localization was determined both in cultured S2 cells and polytene chromosomes. In interphase S2 cells, heterochromatin regions, which are enriched in H3K9me_{2,3}, show strong colocalization with HP1a (Fig. 1A) but very poor staining with α HP1c antibodies (Fig. 1B), indicating that HP1c preferentially localizes to euchromatin being mostly excluded from heterochromatin. Similar results were reported earlier by others (Smothers and Henikoff 2001). Similarly, in polytene chromosomes, HP1a and HP1c also show drastically different patterns of localization, as HP1a localizes to the heterochromatic chromocentre (Fig. 1C) while HP1c is exclusively found at the euchromatic chromosome arms (Fig. 1D). In addition to the chromocentre, HP1a is known to localize to a number of euchromatic sites (Fanti et al. 2003), where it shows no significant colocalization with HP1c (data not shown). These results indicate that, despite their strong similarity, HP1a and HP1c show mutually exclusive patterns of chromosomal distribution.

HP1c localization is restricted to interbands (Fig. 1E), which correspond to gene-rich regions that stain poorly with DAPI, suggesting a contribution to the regulation of gene expression. To analyze the potential contribution of HP1c to gene regulation, we determined the extent of colocalization of HP1c with different histone modifications that correlate with either gene silencing, H3K9me₃ and H3K27me₃, or activation, H3K4me₃ and H3K36me₃ (Fig. 2). HP1c shows partial colocalization with H3K9me₃ (Fig. 2A). Approximately, 50% of HP1c bands colocalize with H3K9me₃, and most frequently, intense HP1c bands show no significant α H3K9me₃ reactivity. On the other hand, colocalization with H3K27me₃ is only very scarce (Fig. 2B). In contrast, HP1c shows a strong colocalization with H3K4me₃ (Fig. 2C), suggesting that HP1c might be involved in transcriptional regulation. Consistent with this hypothesis, HP1c strongly colocalizes with RNAPol II (Fig. 3). Colocalization with the poised form of RNAPol II phosphorylated at Ser 5, Pol IIo^{ser5}, is most extensive, as the majority of bands positive for α HP1c are also positive for α Pol IIo^{ser5} (Fig. 3B). On the other hand, colocalization with the elongating form of RNAPol II phosphorylated at Ser 2, Pol IIo^{ser2}, is much weaker (Fig. 3C), suggesting that HP1c participates at the initial stages of transcription regulation rather than during elongation. Consistent with this hypothesis, HP1c shows only a weak colocalization with H3K36me₃ (Fig. 2D), a modification that occurs during elongation and extends all through transcribed regions (Krogan et al. 2003; Bell et al. 2008).

To further analyze the contribution of HP1c to gene expression, we determined the effects of targeting HP1c to a reporter construct (Fig. 4). In these experiments, we

Figure 1. HP1c localizes to multiple euchromatic sites. The patterns of immunolocalization of HP1a (A,C) and HP1c (B,D), in S2 cells (A,B) and polytene chromosomes (C,D), are shown (in green). Arrows indicate the position of the heterochromatic chromocentre determined by staining with α H3K9me3 and/or α H3K9me2 (in red). (E) The pattern of immunolocalization of HP1c (in red) is presented at a higher magnification to show its localization to interbands. DNA was stained with DAPI (in blue).

took advantage of transgenic flies carrying a reporter *white* transgene containing multiple binding sites for the lacI repressor at the regulatory region (Li et al. 2003). Lines *S9.2* and *157.1* were used, which contain 46 and 256 lacI-repeats respectively. In these lines, expression of fused proteins carrying the lacI-DNA-binding domain results in their targeting to the reporter gene. Previous studies showed that, in general, targeting HP1 proteins to a reporter gene induces silencing (Ayyanathan et al. 2003; Li et al. 2003; Verschure et al. 2005; Smallwood et al. 2007). Actually, in line *S9.2*, expression of HP1a-lacI results in silencing of the reporter gene, which is stronger in males (Fig. 4A). Similar results were reported earlier by others (Li et al. 2003). Expression of HP1b-lacI also induces silencing of the reporter gene, but in contrast, expression of HP1c-lacI does not (Fig. 4A). On the contrary, a slightly increased expression of the reporter *white* gene is observed. These results were confirmed when HP1c-lacI was expressed in line *157.1*, which is more suitable to detect activating effects, as background

expression of the reporter gene is low. As shown in Figure 4B, *white* expression is increased in flies expressing HP1c-lacI. In these experiments, expression of the fused proteins was driven by the *hsp70*-promoter and, therefore, was induced by repeated heat-shock treatments. The observed activation of the reporter gene is specific of HP1c, as no effect is observed in the absence of heat shock (Fig. 4B) or in flies expressing the lacI-DNA-binding domain alone (Fig. 4A,B).

HP1c interacts with the zinc-finger proteins WOC and ROW

Altogether, the results reported above strongly suggest that *Drosophila* HP1c contributes to transcriptional regulation. Next, we asked about the molecular basis of this contribution. To address this question, multiprotein complexes containing HP1c were purified to identify interacting factors that could account for its functional properties. For this purpose, stable S2-cell lines express-

Figure 2. HP1c localizes to active chromatin domains. The extent of colocalization of HP1c (in green) and H3K9me3 (A), H3K27me3 (B), H3K4me3 (C), and H3K36me3 (D) (in red), is determined in polytene chromosomes. Enlarged images are shown at the *bottom* of each panel. Arrows indicate distinct α HP1c (green) and α H3K9me3, α H3K27me3, α H3K4me3, and α H3K36me3 (red) signals. Yellow arrows indicate colocalization.

ing a TAP-HP1c fusion protein were obtained. Purified complexes contain, in addition to HP1c-TAP, a major band of high molecular weight (Fig. 5A, lane HP1c-TAP), which is absent in mock purifications performed from cells expressing the TAP domain alone (Fig. 5A, lane TAP). A few additional weak bands of lower molecular weight are also observed. Next, we proceeded to identification of the high-molecular-weight band mentioned above. LC/MS analysis provided two major hits—WOC (Mascot score of 1031, with 24 identified peptides corresponding to 11% sequence coverage) (Wismar et al. 2000; Warren et al. 2001), and CG8092, which we propose to name Relative-of-WOC (ROW) (Mascot score of 1239, with 66 identified peptides corresponding to 30% sequence coverage) (Supplemental Tables S1, S2). A few other polypeptides were also identified but with much lower scores. Domain structure and organization strongly suggest that both WOC and ROW are transcription factors (Fig. 5B), as they contain multiple zinc-finger and AT-hook domains for sequence-specific DNA bind-

ing and, in addition, ROW contains a C-terminal domain that, enriched in glutamine (Q) residues, resembles transactivation domains of some transcription factors (Triezenberg 1995). WOC is homologous to three human zinc-finger proteins: DXS6673E/ZNF261 (van der Maarel et al. 1996), ZNF198/FIM/RAMP (Popovici et al. 1998; Xiao et al. 1998), and ZNF262 (Sohal et al. 1999). Most remarkably, the C-terminal domain (~300 amino acids) is highly conserved in the three human proteins as well as in WOC. On the other hand, ROW shows no significant homology with any known protein.

Coimmunoprecipitation experiments confirmed the interaction between HP1c, WOC, and ROW, as immunoprecipitation with α WOC antibodies results in quantitative coprecipitation of both HP1c and ROW (Fig. 5C). No coimmunoprecipitation of HP1c and ROW was observed when the extracts were treated with unrelated antibodies (α DDP1) or when no antibodies were added. Moreover, addition of α WOC antibodies does not result in coprecipitation of HP1a (Fig. 5C). Consistent with

Figure 3. HP1c colocalizes with the poised form of RNAPol II, Pol Ilo^{ser5}. The extent of colocalization of HP1c (in green) and unphosphorylated RNAPol II (A), Pol Ilo^{ser5} (B), and Pol Ilo^{ser2} (C) (in red), is determined in polytene chromosomes. Enlarged images are shown at the *bottom* of each panel. Arrows indicate distinct αHP1c (green) and αRNAPol IIa, α Pol Ilo^{ser5}, and α Pol Ilo^{ser2} (red) signals. Yellow arrows indicate colocalization.

these results, both HP1c and ROW show the most extensive colocalization with WOC, with virtually all bands positive for αHP1c and αROW being also positive for αWOC and vice versa (Fig. 6A,B). In addition, targeting HP1c-lacI to the lacI-repeats of line 157.1 results in ectopic recruitment of both WOC and ROW, as additional αWOC and αROW signals are detected at the position corresponding to the lacI-repeats (Fig. 6C,D). No such recruitment is observed in flies expressing the lacI-DNA-binding domain alone (Fig. 6C,D).

WOC and ROW mediate chromosomal association of HP1c

The results discussed above indicate that HP1c interacts with the zinc-finger proteins WOC and ROW, which are likely to bind DNA sequences specifically. Therefore, it is possible that binding of HP1c to chromatin is mediated by WOC and ROW. To test this hypothesis, we analyzed chromosomal association of HP1c in *woc* and

row mutants. For this purpose, we used *woc*^{RNAi} and *row*^{RNAi} knockdown transgenic flies, which carry a UAS_{GAL4} construct expressing a synthetic hairpin from the coding region of either *woc* or *row* that, upon crossing with flies expressing GAL4, generates siRNAs to silence expression of the corresponding gene. *woc*^{RNAi} and *row*^{RNAi} show strong silencing of the corresponding gene when crossed to flies carrying a ubiquitous *Actin5C*-GAL4 driver, so that, at the third-instar larvae stage, corresponding mRNA levels are reduced to ~40% of those observed in control larvae (Supplemental Fig. S1A,B). Under these conditions, both mutations show high lethality at the pupae stage, which is stronger in *woc*^{RNAi}.

Chromosomal association of HP1c is strongly compromised in *woc*^{RNAi} and *row*^{RNAi} mutant polytene chromosomes (Fig. 7A). In these experiments, depletion of WOC and ROW was induced in salivary glands by crossing *woc*^{RNAi} and *row*^{RNAi} lines to a *lio*-GAL4 line, where the *limbo* promoter drives GAL4 expression. Mutant salivary glands were then mixed and squashed together

Figure 4. Targeting HP1c to a reporter *white* transgene increases its expression. (A) The eye phenotype of *S9.2* flies expressing the indicated fused proteins (+) is compared with that of siblings where no fused protein is expressed (-). Expression was induced by heat-shock treatment. (B) Similar experiments as in A, but performed in *157.1* flies. Results are presented when expression of HP1c-lacI was induced by heat shock (*top*) and when no heat-shock treatment was applied (*middle*).

with glands prepared from control wild-type larvae, which carry a UAS_{GAL4} -H2B::GFP construct and, therefore, incorporate H2B-GFP in polytene chromosomes. In

this way, mutant and control polytene chromosomes, which are identified by their staining with α GFP antibodies, are immunostained and observed under exactly

Figure 5. HP1c interacts with WOC and ROW. (A, lane *TAP-HP1c*) Multiprotein complexes containing TAP-HP1c were purified and analyzed by SDS-PAGE. Lane *TAP* corresponds to a mock purification performed from cells expressing the TAP domain alone. Lanes *M* correspond to molecular-weight markers. The position of the high-molecular-weight band that, as shown by LC/MS analysis, corresponds to WOC and ROW is indicated. The position of the TAP-HP1c bait is also indicated. Bands labeled with an asterisk correspond to IgGs. (B) Structural organization of WOC, ROW, and the three human homologs of WOC (DXS6673E/ZNF261, ZNF198/FIM/RAMP, and ZNF262). The positions of the zinc-finger (ZNF) and AT-hook domains (AT) are indicated. P indicates a proline-rich repeat conserved in WOC and its human homologs. HC corresponds to the highly conserved C-terminal domain present in WOC and its human homologs. Q corresponds to the C-terminal glutamine (Q)-rich domain present in ROW. (C) HP1c and ROW coimmunoprecipitate with WOC. Nuclear extracts were subjected to immunoprecipitation with α WOC antibodies (lane 4) or with control α DDP1 antibodies (lane 3), and analyzed by Western-blot using α HP1c (*top*), α ROW (*middle*), and α HP1a (*bottom*). Lane 2 corresponds to a mock immunoprecipitation where no antibodies were added. Lane 1 corresponds to 10% of the input material used for immunoprecipitation.

Figure 6. HP1c and ROW colocalize with WOC. (A,B) The extent of colocalization of WOC (in red) with HP1c (A) and ROW (B) (in green) is presented. Enlarged images are shown at the *bottom*. Arrows indicate distinct α HP1c (green), α ROW (green), and α WOC (red) signals. Yellow arrows indicate colocalization. (C,D) Targeting of HP1c-lacI to the lacI insertion of 157.1 flies results in ectopic recruitment of WOC (C) and ROW (D). The patterns of immunolocalization of WOC and ROW (in red) are presented at the region of the lacI insertion in flies expressing HP1c-lacI (panel HP1c-lacI) and lacI alone (panel lacI). The patterns obtained with α lacI antibodies (in green) are also presented. Big arrows indicate the position of the α lacI signal, marking the position of the lacI insertion that colocalizes with additional α WOC and α ROW signals when HP1c-lacI is expressed. the same experimental conditions. As shown in Figure 7A, *woc*^{RNAi} and *row*^{RNAi} mutant chromosomes show highly reduced reactivity with α HP1c antibodies while control polytenes show strong α HP1c reactivity, strongly suggesting that both WOC and ROW are required for binding of HP1c to chromatin.

Lack of HP1c observed in *woc*^{RNAi} and *row*^{RNAi} polytene chromosomes could also reflect a contribution to synthesis, and/or stability, of HP1c. To address this question, *woc*^{RNAi} and *row*^{RNAi} lines were crossed to a *ptc*-GAL4 line, where GAL4 expression is driven by the *patched* promoter that, in the wing disc, is specifically active at the anterior/posterior (A/P)-boundary. Therefore, in these experiments, depletion of WOC and ROW was specifically induced at the A/P-boundary in the wing disc. Under these conditions, *woc*^{RNAi} and *row*^{RNAi} mutant cells of the A/P-boundary show reduced HP1c levels

(Fig. 8A). It must be noticed, however, that a much stronger effect is observed when similar experiments are performed in an *hp1c*^{RNAi} mutant background (Fig. 8A), where depletion of HP1c is most efficient (Fig. 8C; Supplemental Fig. S1C). No effect is detected in a control *hp1a*^{RNAi} line (Fig. 8A). Similar results were obtained when WOC and ROW were depleted ubiquitously, by crossing *woc*^{RNAi} and *row*^{RNAi} to an *Actin5C*-GAL4 line, and the effects on HP1c levels determined by Western-blot (Fig. 8B). Under these circumstances, depletion of WOC and ROW results in a moderate decrease of HP1c. On the other hand, HP1c mRNA levels are only slightly reduced in *woc*^{RNAi} and *row*^{RNAi} (Fig. 8C), strongly suggesting that reduced HP1c protein levels observed in the mutants reflects destabilization of the protein due, most likely, to its inability to bind chromatin. Similar effects were reported for HP1a and Polycomb (PC), when their

Figure 7. Binding of HP1c to chromatin is mediated by WOC and ROW. (A) The pattern of immunolocalization of HP1c (in green) is presented in polytene chromosomes obtained from *woc^{RNAi}*; *lio-GAL4* (panel *woc^{RNAi}*) and *row^{RNAi}*; *lio-GAL4* mutant larvae (panel *row^{RNAi}*). Polytene chromosomes obtained from control *UAS_{GAL4}-H2B::GFP*; *lio-GAL4* larvae were mixed and squashed together with mutant polytene chromosomes. Control wild-type chromosomes (wt) are identified by their reactivity with α GFP antibodies (in red). (B) HP1c-lacI was overexpressed in *woc^{RNAi}*; *Act5C-GAL4* and in control *gfp^{RNAi}*; *Act5C-GAL4* flies. Binding of HP1c-lacI was determined in polytene chromosomes by immunostaining with α lacI antibodies (in green). Control wild-type chromosomes (wt) are identified by their reactivity with α WOC antibodies (in red). (C) Similar experiments as in B, but HP1c-lacI was overexpressed in *row^{RNAi}*; *Act5C-GAL4* (panel *row^{RNAi}*) and in control *gfp^{RNAi}*; *Act5C-GAL4* flies (panel wt). In this case, mutant and control chromosomes were analyzed separately. As a control, the immunolocalization patterns obtained with α GAGA antibodies (in red) are shown. DNA was stained with DAPI (in blue). Arrows indicate the position of the chromocentre.

binding to chromatin was impaired (Swaminathan et al. 2005; Tan et al. 2007).

To further confirm the contribution of WOC and ROW to recruitment of HP1c, we performed overexpression experiments, where HP1c-lacI was expressed in *woc^{RNAi}* and *row^{RNAi}* mutants, and its ability to bind polytene chromosomes compared with that observed when overexpression was carried out in control wild-type flies. When HP1c-lacI was expressed in *woc^{RNAi}*, polytene chromosomes from mutant and control larvae were squashed together and immunostained with α lacI antibodies to determine binding of HP1c-lacI (Fig. 7B). In control polytenes, which are identified by their staining with α WOC antibodies, overexpressed HP1c-lacI binds to multiple euchromatic sites, as endogenous HP1c does. On the other hand, in *woc^{RNAi}* chromosomes, binding of

HP1c-lacI to euchromatin is impaired. Similar results were obtained when HP1c-lacI was expressed in *row^{RNAi}* (Fig. 7C). In this case, reactivity with α GAGA was used as a control for comparison since mutant and control wild-type chromosomes were observed separately. As in *woc^{RNAi}*, no significant α lacI reactivity is observed at euchromatin in *row^{RNAi}* chromosomes. On the other hand, binding of WOC and ROW is not significantly affected in mutant *hp1c^{RNAi}* polytene chromosomes (Fig. 9A,B), indicating that HP1c is not required for binding of WOC and ROW. Moreover, WOC and ROW are reciprocally required for binding to chromatin, as binding of ROW to chromatin is severely impaired in *woc^{RNAi}* chromosomes (Fig. 9C) and, vice versa, binding of WOC is also strongly impaired in *row^{RNAi}* chromosomes (Fig. 9D). Altogether, these results strongly indicate that

Figure 8. HP1c protein levels are decreased in *woc*^{RNAi} and *row*^{RNAi}. (A) Immunostaining with α HP1c antibodies (in green) is presented in wing imaginal discs obtained from *hp1c*^{RNAi}; *ptc*-GAL4 (panel *hp1c*^{RNAi}), *woc*^{RNAi}; *ptc*-GAL4 (panel *woc*^{RNAi}), *row*^{RNAi}; *ptc*-GAL4 (panel *row*^{RNAi}), and *hp1a*^{RNAi}; *ptc*-GAL4 larvae (panel *hp1a*^{RNAi}). The arrows indicate the A/P-boundary where the *ptc*-promoter is specifically active. (B) HP1c levels are analyzed by Western-blot with α HP1c antibodies in extracts prepared from *woc*^{RNAi}; *Act5C*-GAL4 (lanes *woc*^{RNAi}), *row*^{RNAi}; *Act5C*-GAL4 (lanes *row*^{RNAi}), and control wild-type larvae (lanes wt). Two increasing amounts of extract were analyzed in each case (lanes 1,2). The signal obtained with α Actin antibodies was used as loading control for normalization. (C) Quantitative RT-PCR analysis of the levels of HP1c mRNA observed in *woc*^{RNAi}; *Act5C*-GAL4 (column *woc*^{RNAi}), *row*^{RNAi}; *Act5C*-GAL4 (column *row*^{RNAi}), and control wild-type larvae (column wt). Results obtained with *hp1c*^{RNAi}; *Act5C*-GAL4 larvae (column *hp1c*^{RNAi}) are also included for comparison. Relative HP1c mRNA expression was determined in relation to GAP expression.

WOC and ROW form obligated hetero-oligomers that, in turn, bind HP1c and recruit it to specific genomic locations.

Interestingly, overexpression of HP1c-lacI results in its misincorporation to heterochromatin, as it is also detected at the heterochromatic chromocentre (Fig. 7B,C). Binding to heterochromatin, however, is not impaired in *woc*^{RNAi} and *row*^{RNAi} chromosomes, suggesting that it occurs independently of WOC and ROW. It must also be noticed that mislocalization of HP1c-lacI to heterochromatin induces recruitment of WOC (Fig. 7B) that, otherwise, is excluded from heterochromatin (Fig. 6A).

That binding of HP1c to chromatin is strictly dependent on the zinc-finger proteins WOC and ROW was unexpected, as HP1c contains an N-terminal chromodomain that, being homologous to that of HP1a, could mediate binding to H3K9me2,3 (Smothers and Henikoff 2001). In fact, all residues directly involved in this interaction are conserved in the chromodomain of HP1c. Actually, in vitro, HP1c specifically recognizes H3K9me2,3 through its chromodomain (Fig. 10). As judged by Far-Western analysis, HP1c binds endogenous, but not recombinant, histone H3 (Fig. 10A). This binding (1) depends on the N-terminal domain of histone H3, as it is abolished after mild digestion with trypsin to cleave the N-terminal tail (Fig. 10B); (2) involves recognition of H3K9me3, as it is competed by a H3K9me3-peptide but not by the equivalent unmethylated-peptide (Fig. 10C); and (3) is mediated by the chromodomain of HP1c, as no binding is observed with HP1c^{ΔCHROMO}, a truncated

form missing the chromodomain, while the chromodomain by itself, HP1c^{CHROMO}, shows significant binding (Fig. 10D). Moreover, HP1c is also capable of binding H3K9me2,3 in mononucleosomes (Fig. 10E). In these experiments, total mononucleosomes were subjected to pull-down assays with GST-HP1c and GST-HP1a fusion proteins. As shown in Figure 10E, mononucleosomes bound by GST-HP1c are strongly enriched in both H3K9me3 and H3K9me2 when compared with the input mononucleosomes. Enrichment is similar to that observed in mononucleosomes bound by GST-HP1a. On the other hand, mononucleosomes bound by both GST-HP1c and GST-HP1a show no significant enrichment in H3K9me1 as well as in a number of other histone modifications (i.e., H3K27me1,2,3, H4K20me1,2,3) (data not shown). These results indicate that, in vitro, HP1c and HP1a bind chromatin on the basis of a common molecular mechanism; namely, recognition of H3K9me2,3.

HP1c cooperates with WOC and ROW to regulate gene expression

The results reported above show that HP1c associates with the zinc-finger proteins WOC and ROW that, in addition, mediate its binding to chromatin. Next, we asked whether HP1c, WOC, and ROW are also functionally linked. Expression profiling was used to determine the actual contribution of HP1c, WOC, and ROW to gene expression. For this purpose, *hp1c*^{RNAi}, *woc*^{RNAi}, and *row*^{RNAi} lines were crossed to flies carrying an ubiqui-

Figure 9. WOC and ROW are reciprocally required for binding to chromatin. (A,B) The patterns of immunolocalization of WOC (A) and ROW (B) (in red) are presented in polytene chromosomes obtained from mutant *hp1c^{RNAi}*; *Act5C-GAL4* larvae. In A, polytene chromosomes obtained from control wild-type larvae were mixed and squashed together with mutant *hp1c^{RNAi}* polytene chromosomes, which are identified by their lack of reactivity with α HP1c antibodies (in green). In B, mutant and control wild-type (wt) chromosomes were analyzed separately. As a control, the immunolocalization patterns obtained with α GAGA antibodies (in green) are shown. (C) The pattern of immunolocalization of ROW (in green) is presented in polytene chromosomes obtained from mutant *woc^{RNAi}*; *Act5C-GAL4* larvae. Polytene chromosomes obtained from control wild-type larvae were mixed and squashed together with mutant *woc^{RNAi}* polytene chromosomes, which are identified by their lack of reactivity with α WOC antibodies (in red). (D) The pattern of immunolocalization of WOC (in red) is presented in polytene chromosomes obtained from mutant *row^{RNAi}*; *Act5C-GAL4* larvae. Polytene chromosomes obtained from control wild-type larvae were mixed and squashed together with mutant *row^{RNAi}* polytene chromosomes, which are identified by their lack of reactivity with α ROW antibodies (in green). DNA was stained with DAPI (in blue).

tous *Act5C-GAL4* driver, and total RNA was prepared from blue staged male larvae. Under these experimental conditions, a number of nonspecific factors could also have an effect on gene expression, so that their contribution needed to be subtracted. These factors include two genomic insertions: the UAS_{GAL4} construct expressing the synthetic hairpin against the corresponding gene and the *Act5C-GAL4* insertion. Moreover, in the mutants, the RNAi pathway is hyperactivated and siRNAs are generated to a high concentration, which could also have an effect on gene expression. For each mutant condition, the original UAS_{GAL4}-hairpin line was used as control, to account for nonspecific effects due to the corresponding insertion. In addition, to account for nonspe-

cific effects due to the *Act5C-GAL4* insertion and hyperactivation of RNAi, two other controls were used: an *Act5C-GAL4* line carrying an UAS_{GAL4}-hairpin construct against an unrelated gene (GFP), and the original line carrying the UAS_{GAL4}-hairpin insertion against GFP.

Differential expression was measured with an interval distance that provides a conservative approach to the analysis of complex samples that, as in the case described here, contain different sources of background noise (see the Supplemental Material for details). Briefly, for each gene, the interval of expression in the mutant (determined from the values observed in independent biological replicas) is compared with the interval of ex-

Figure 10. HP1c binds H3K9me2,3 in vitro. (A) Binding of His-tagged HP1c to endogenous histone H3, obtained from S2 cells, (panel H3_{S2}), as well as recombinant histone H3, expressed in bacteria, (panel H3_{REC}), is analyzed by Far-Western using α His antibodies (shown at top). Lanes 1 and 2 correspond to increasing amounts of H3. Western analysis with α H3 antibodies is presented at the bottom, as a loading control. (B) Nucleosomes prepared from S2 cells were treated with trypsin, to cleave the histone N-terminal tails (lanes 1) or not (lanes 2), and then binding of his-tagged HP1c was analyzed by Far-Western using α His antibodies. Staining with Ponceau of the filter before hybridization with α His antibodies is presented on the left. The position corresponding to histone H3 is indicated. (C) Binding of His-tagged HP1c (panel HP1c) or HP1a (panel HP1a) to endogenous histone H3 was analyzed by Far-Western using α His antibodies. Binding was performed in the presence of 50 μ M of a peptide from the H3 N-terminal tail trimethylated at K9 (lanes 3) or unmethylated (lanes 2). Lanes 1 correspond to the binding observed in the absence of any added competitor. (D) Binding to endogenous H3 of GST-tagged HP1c (lane 2) and truncated forms containing only the N-terminal chromodomain, HP1c^{CHROMO} (amino acids 1–62) (lane 4), or missing it, HP1c^{ΔCHROMO} (amino acids 63–237) (lane 3), is analyzed by Far-Western using α GST antibodies. Lane 1 corresponds to binding of GST-tagged HP1a. (E) Pull-down assays of total mononucleosomes prepared from S2 cells were performed with GST-HP1c and GST-HP1a fused proteins, and bound mononucleosomes analyzed by Western using α H3K9me3, α H3K9me2, α H3K9me1, and α H3 antibodies. Lanes 1 and 2 correspond to increasing amounts of bound mononucleosomes. INPUT corresponds to 10% of mononucleosomes used for pull-down assays.

pression observed in the control samples (determined from the highest and lowest expression observed in all control samples). This defines, for each gene, a distance between intervals of expression in the mutant versus the controls, which is then divided by an estimate of the standard deviation. The distance is set to zero if the intervals overlap. Table 1 summarizes, for each mutant background, the number of differentially expressed genes

observed at increasing cut-off values of the interval distance. At low cut-off values (>0), a similar number of differentially expressed genes are found in all three mutants. However, as the cut-off value is increased, and hence less false positives are expected, a higher number of genes is found in *woc*^{RNAi} and *row*^{RNAi} than in *hp1c*^{RNAi}, suggesting that WOC and ROW regulate more genes than HP1c.

Given the interactions observed between HP1c, WOC, and ROW, we anticipate that these three factors regulate a common set of genes, so that the patterns of differentially expressed genes observed in the three mutants could correlate. To test this hypothesis, we measured the correlation between the patterns of differentially expressed genes in the mutants by computing Spearman's rank correlation coefficient between the interval distances. As shown in Table 2, the patterns of differentially expressed genes show correlations that are much higher than those expected under the hypothesis that no genes are coregulated (P -value $< 1.0 \times 10^{-8}$). Next, to determine to what extent the gene expression programs executed by HP1c, WOC, and ROW overlap, we assessed the range of Spearman's correlation values that would be expected under complete coregulation. For this purpose, a simulation study was carried out under the assumption that all genes are coregulated and that the change in expression relative to the controls is the same for the three mutants. As shown in Table 2, the observed correlation between *woc*^{RNAi} and *row*^{RNAi} falls within the expected interval for complete coregulation, supporting that WOC and ROW execute a common gene expression program. On the other hand, correlations observed between *hp1c*^{RNAi} and either *woc*^{RNAi} or *row*^{RNAi} are lower than expected for complete coregulation, an observation that could be anticipated from the higher number of differentially expressed genes observed in *woc*^{RNAi} and *row*^{RNAi} than in *hp1c*^{RNAi} (Table 1). More relevant, in this case, is the circumstance that virtually all differentially expressed genes in *hp1c*^{RNAi} turn out to be differentially expressed in both *woc*^{RNAi} and *row*^{RNAi} (Table 3). For this analysis, genes were classified into nine different categories according to whether they are not differentially expressed in any of the mutants or they change expression in one, two, or the three mutant conditions. As shown in Table 3, most of the genes are not differentially expressed in any of the three mutants. Consistent with the strong correlation observed between

Table 1. Number of differentially expressed genes observed in *hp1c*^{RNAi}, *woc*^{RNAi}, and *row*^{RNAi} mutants as a function of increasing cut-off value of the interval distance

Cut-off	<i>hp1c</i> ^{RNAi}		<i>woc</i> ^{RNAi}		<i>row</i> ^{RNAi}	
	Down	Up	Down	Up	Down	Up
>0	1142	1002	1319	1148	1165	1642
>1.0	192	149	349	214	259	367
>2.0	53	30	103	48	74	66

The number of genes up-regulated (up) or down-regulated (down) are indicated.

Table 2. Spearman's correlation between the patterns of differential gene expression of *hp1c^{RNAi}*, *woc^{RNAi}*, and *row^{RNAi}* mutants

	Observed	No coregulation	Complete coregulation
<i>hp1c^{RNAi}</i> vs <i>woc^{RNAi}</i>	0.14	(−0.02, 0.02)	(0.22, 0.25)
<i>hp1c^{RNAi}</i> vs <i>row^{RNAi}</i>	0.10	(−0.02, 0.02)	(0.22, 0.26)
<i>woc^{RNAi}</i> vs <i>row^{RNAi}</i>	0.30	(0.00, 0.04)	(0.28, 0.32)

The observed correlations are compared with the range expected if no genes were coregulated and if all were coregulated.

woc^{RNAi} and *row^{RNAi}*, a high proportion (92.4%) of total differentially expressed genes change expression both in *woc^{RNAi}* and *row^{RNAi}*. On the other hand, most of the genes that are differentially expressed in *hp1c^{RNAi}* also change expression in both *woc^{RNAi}* and *row^{RNAi}*, as only a low proportion are affected solely in *hp1c^{RNAi}* and no genes are differentially expressed in *hp1c^{RNAi}* and in only one of the other two mutants. Actually, 14.1% of total differentially expressed genes change expression in all three mutants, which accounts for 94.6% of the genes that are differentially expressed in *hp1c^{RNAi}*. These results indicate that a vast majority of genes regulated by HP1c are also regulated by both WOC and ROW, which is fully consistent with the interactions described above. It must be noticed, however, that many differentially expressed genes (78.3%) change in *woc^{RNAi}* and *row^{RNAi}* but not in *hp1c^{RNAi}*.

Next, we asked about the characteristics of the expression program coregulated by HP1c, WOC, and ROW. This analysis was restricted to the 158 genes that were found differentially expressed in the same direction in all three mutants, as they stand the highest probability of being truly coregulated by the three factors (Supplemental Table S3). Gene ontology (GO) analysis of this set of genes shows no statistically significant enrichment in any particular annotation after correction for multiple testing. To some extent, this observation was not unexpected considering the complexity of the samples used in our analysis, total RNA prepared from whole larvae. Clustering analysis, however, shows a number of associations of more than three genes sharing common GO annotations (Fig. 11A). Notably, a cluster of genes implicated in nervous system development and morphogenesis is observed. These include the transcription factor *prospero* (*pros*), the dynein motor *Dhc64C*, and the axon guidance factors, *trio* and *NetrinA* (*NetA*). Actually, a detailed examination of the 158 genes differentially expressed in the same direction in the three mutants, shows that, regardless of their actual GO annotations, 35 have attributed functions related to various aspects of development and functionality of the nervous system (Fig. 11B), including neurogenesis, synapsis formation and function, and sensory perception. Similar results are obtained when all genes differentially expressed in *woc^{RNAi}* and *row^{RNAi}* mutants are analyzed. In this case, an additional cluster of genes involved in imaginal discs development is observed (data not shown). Altogether, these results suggest that, at least in part, HP1c, WOC,

and ROW execute their genetic program in the context of the nervous system.

Discussion

Here, we report on the interaction between *Drosophila* HP1c and the zinc-finger proteins WOC and ROW. Our results indicate that both WOC and ROW copurify with HP1c. Coimmunoprecipitation experiments corroborate the interaction of WOC with HP1c and ROW. Moreover, in polytene chromosomes, HP1c and ROW extensively colocalize with WOC, and targeting HP1c to an ectopic construct results in recruitment of both WOC and ROW. Altogether, these results indicate that HP1c, WOC, and ROW are components of a distinct multiprotein complex. HP1c–WOC interaction is likely to be direct, as WOC contains a canonical PxVxL motif (¹⁵³⁶PHVLL¹⁵⁴⁰), which is known to mediate binding to the chromo-shadow domain of HP1 proteins (Lechner et al. 2000, 2005; Smothers and Henikoff 2000). This motif is located within the highly conserved C-terminal HC domain of WOC, being also present in the three human homologs. ROW also contains several variant PxVxL motifs, suggesting that it might also bind directly to HP1c. In agreement with these observations, euchromatic localization of HP1c depends on the C-terminal chromo-shadow domain (Smothers and Henikoff 2001), strongly suggesting that it mediates interaction with WOC and ROW.

Binding of HP1c to chromatin relies on the zinc-finger proteins, WOC and ROW

Here, we also show that binding of HP1c to chromatin depends on WOC and ROW that, on the other hand, are reciprocally required for binding to chromatin. Domain structure and organization indicate that WOC and ROW are sequence-specific DNA-binding proteins. These results indicate that chromosomal association of HP1c is largely determined by the recognition of specific DNA sequences, which is in contrast to the situation observed in the case of *Drosophila* HP1a, or mammalian HP1α, where chromosomal association was found to depend on

Table 3. Percentage of genes differentially expressed in none, one, two, and all three *hp1c^{RNAi}*, *woc^{RNAi}*, and *row^{RNAi}* mutants

(DE) Differentially expressed; (=) not differentially expressed.

Figure 11. HP1c, WOC and ROW coregulate a common gene expression program that, in part, is executed in the context of the nervous system. (A) Gene-cluster analysis of the 158 genes that are differentially expressed in the same direction in all three mutants. Associations of more than three genes sharing common GO annotations are presented. (B) Out of the 158 genes that are differentially expressed in the same direction in the three mutants, 35 have attributed functions related to development and functionality of the nervous system (neurogenesis, synapsis formation and function, and sensory perception).

the recognition of a specific pattern of histone modifications; namely, H3K9 methylation (Hiragami and Festenstein 2005; Hediger and Gasser 2006). Several HP1 proteins, including HP1a and HP1 α , were reported to interact with a number of transcription factors, replication proteins, and chromatin assembly complexes (Hiragami and Festenstein 2005; Hediger and Gasser 2006; Lomberg et al. 2006). Yet, it is unclear whether these interactions mediate recruitment of HP1 to specific sites, and/or in response to particular processes, or they actually take place after recruitment to regulate their functions. What is striking in the case of *Drosophila* HP1c is that its binding to chromatin is strictly dependent on DNA-binding proteins. Our results, however, also show that, through the chromodomain, HP1c efficiently binds H3K9me2,3 in vitro. Actually, overexpression of HP1c-lacI leads to its mislocalization to heterochromatin, likely reflecting binding to H3K9me2,3. In this context, it must be noticed that HP1c shows a partial colocalization with H3K9me3. However, binding of HP1c at these sites is in general weak, being also obliterated in the absence of WOC and ROW. HP1 proteins have been reported to interact with different histone methyltransferases (HMTs), being involved in their recruitment to specific sites (Hiragami and Festenstein

2005; Hediger and Gasser 2006; Lomberg et al. 2006). Therefore, it is possible that H3K9 methylation at these sites is actually the consequence of HP1c binding. Altogether, these observations indicate that recognition of H3K9me2,3 is not a major determinant of the association of HP1c with chromatin in vivo. Consistent with this interpretation, replacing the chromodomain of HP1c by that of HP1a does not alter its chromosomal distribution (Smothers and Henikoff 2001). The interaction with WOC and ROW does not appear to hinder the chromodomain from binding H3K9me2,3 since overexpression of HP1c-lacI brings both HP1c and WOC to heterochromatin. Several other possibilities can account for the inability of HP1c to bind H3K9me2,3 in vivo. The interaction of HP1c with WOC and ROW might be of higher affinity than the interaction with H3K9me2,3. In addition, post-translational modifications could regulate these interactions. It is also possible that HP1c is actively excluded from heterochromatin. Whether binding to H3K9me2,3 plays a role at any stage during development or cell cycle progression remains, however, to be determined.

HP1a and HP1b also localize to euchromatin, yet they show strong binding to heterochromatin. Therefore, WOC and ROW could also play a role in binding of HP1a

and HP1b to euchromatin. In fact, euchromatic localization of HP1b is decreased in both *woc^{RNAi}* and *row^{RNAi}* mutants (Supplemental Fig. S2). This effect, however, is much weaker than that observed in the case of HP1c. On the other hand, binding of HP1a to euchromatin is not grossly altered in *woc^{RNAi}* and *row^{RNAi}* mutants (Supplemental Fig. S3), though its association to some specific loci, such as at the 31C region, appears to be affected (data not shown). On the other hand, binding of HP1a and HP1b to heterochromatin, which depends on H3K9me_{2,3}, is not significantly affected in *woc^{RNAi}* and *row^{RNAi}* mutants (Supplemental Figs. S2, S3). Similarly, mislocalization of overexpressed HP1c-lacI to heterochromatin, which likely reflects binding to H3K9me_{2,3}, is not affected either in *woc^{RNAi}* and *row^{RNAi}* mutants.

Altogether, these observations suggest that, in *Drosophila*, HP1 proteins could be recruited to chromatin by at least two independent mechanisms: (1) recognition of H3K9me_{2,3}, which is instrumental in heterochromatin binding, and (2) interaction with sequence-specific DNA-binding proteins, which mediate euchromatic localization of HP1c and, perhaps, of HP1b and HP1a to some specific loci. Actually, the interaction of HP1 proteins with DNA-binding proteins might be more frequent than anticipated. In fact, in *C. elegans*, HPL-2 was found to interact with LIN-13 (Coustham et al. 2006), a sequence-specific DNA-binding protein containing multiple zinc-finger domains.

The contribution of HP1c to gene expression

Here, we report that HP1c localizes at multiple active chromatin domains and cooperates with WOC and ROW, which show features characteristic of transcription factors, to regulate gene expression. Moreover, targeting HP1c to a reporter construct promotes expression of the reporter gene. This effect is specific of HP1c, as targeting both HP1a and HP1b induce silencing. These results indicate that, rather than as a silencing factor, HP1c acts as a transcriptional regulator that is recruited to chromatin by sequence-specific DNA-binding proteins.

Other HP1 proteins have also been shown to contribute to the regulation of gene expression, yet their presence is generally associated to silencing. These include *Drosophila* HP1a, which is required for proper expression of most heterochromatic genes as well as a few euchromatic genes (Hearn et al. 1991; Clegg et al. 1998; Lu et al. 2000; Piacentini et al. 2003; Cryderman et al. 2005; De Lucia et al. 2005). Mammalian HP1 γ has also been shown to localize at active genes in a murine erythroid cell line (Vakoc et al. 2005). In these cases, presence of HP1 appears to be implicated in stabilizing RNA transcripts, or in another RNA-processing event occurring during elongation. In the case of HP1c, however, colocalization with the poised RNAPol II form, Pol Ilo^{ser5}, is much stronger than with the elongating form, Pol Ilo^{ser2}, suggesting that HP1c acts at the promoter level rather than during elongation. Consistent with this hypothesis, HP1c shows a much stronger colocalization with

H3K4me₃, a modification that occurs at promoters, than with H3K36me₃, which occurs all through transcribed regions and incorporates during elongation. In full agreement with our results, WOC also shows extensive colocalization with Pol Ilo^{ser5}, which is stronger than with Pol Ilo^{ser2} (Raffa et al. 2005). These results favor a contribution to the regulation of genes containing poised RNAPol II. Actually, recent studies show that the presence of poised RNAPol II at promoters is more frequent than anticipated, particularly on developmental control genes (Muse et al. 2007; Zeitlinger et al. 2007). Interestingly, a high proportion of genes coregulated by HP1c, WOC, and ROW act during development and morphogenesis.

The precise molecular mechanism(s) underlying the contribution of HP1c to transcription regulation remains to be determined. However, a contribution to RNAPol II recruitment appears unlikely since, in the absence of WOC, RNAPol II recruitment is not affected (Raffa et al. 2005). A contribution to the regulation of poised RNAPol II is also uncertain, as no gross changes in the levels of Pol Ilo^{ser5} and Pol Ilo^{ser2} are observed in *woc*-null mutants by either immunostaining (Raffa et al. 2005) or Western analysis (data not shown). It is possible, however, that HP1c/WOC/ROW act only on a reduced subset of genes containing poised RNAPol II. It must also be noticed that HP1c likely participates both in promoting and inhibiting transcription. In fact, among the 158 genes that are differentially expressed in the same direction in *hp1c^{RNAi}*, *woc^{RNAi}*, and *row^{RNAi}* mutants, the number of up-regulated and down-regulated genes is similar, 80 in front of 78. Moreover, consistent with a contribution to repression, out of the 35 genes that are coregulated by HP1c, WOC, and ROW in the context of the nervous system, a significantly higher number of genes are found up-regulated than down-regulated in the mutants, 22 versus 13. On the other hand, targeting HP1c to a reporter, though modestly, increases its expression. Altogether, these observations suggest that, depending on the actual functional/promoter context, HP1c can be engaged in either promoting or inhibiting transcription.

The patterns of differentially expressed genes observed in *woc^{RNAi}* and *row^{RNAi}* mutants show a very strong correlation, indicating that WOC and ROW share a common gene expression program. In addition, our results show that genes regulated by HP1c are also regulated by both WOC and ROW. On the other hand, a high proportion (78.3%) of differentially expressed genes change expression both in *woc^{RNAi}* and *row^{RNAi}* but not in *hp1c^{RNAi}*, suggesting that WOC and ROW could also regulate gene expression independently of HP1c. However, the extensive colocalization observed between WOC, ROW, and HP1c argues against this possibility. On the other hand, our results show that HP1c protein levels are significantly decreased in *woc^{RNAi}* and *row^{RNAi}* mutants. In this scenario, stronger synergistic effects would be expected in *woc^{RNAi}* and *row^{RNAi}* mutants than in *hp1c^{RNAi}*, which could result in more genes being differentially expressed. Consistent with this hy-

pothesis, a major proportion of genes that are differentially expressed in all three mutants shows stronger changes in *woc^{RNAi}* and *row^{RNAi}* than in *hp1c^{RNAi}*. Actually, out of the 158 genes that are differentially expressed in the same direction in all three mutants, 77 had smaller changes in *hp1c^{RNAi}* than in *woc^{RNAi}* or *row^{RNAi}*, a statistically significant higher number than the 52.6 genes expected under the assumption that the magnitude of change is the same in all three mutants (P -value < 0.0001).

Clustering analysis suggests that the gene expression program coregulated by HP1c, WOC, and ROW is executed, at least in part, in the context of the nervous system. In agreement with this hypothesis, expression of *woc* and *row* is high in the nervous system during embryogenesis and larval development, and mutant larvae have reduced brains (Wismar et al. 2000; Brody et al. 2002). Furthermore, one of the human homologs of WOC, DXS6673E/ZNF261, is implicated in a form of X-linked mental retardation (van der Maarel et al. 1996).

HP1c and telomere function

Others reported that WOC regulates telomere function, as it is required to prevent chromosomal end-to-end fusions (Raffa et al. 2005). The physical and functional interactions between WOC, HP1c, and ROW suggest that HP1c and ROW might also regulate telomere function. Actually, at telomeres, colocalization of WOC with HP1c and ROW is also most extensive, with all detectable α WOC bands overlapping with α HP1c and α ROW bands and vice versa (Supplemental Fig. S4). However, the incidence of telomere fusions in *hp1c^{RNAi}* and *row^{RNAi}* mutants is low, being similar to that observed in control flies, carrying an UAS-hairpin construct against an unrelated gene, GFP (data not shown). This is likely the consequence of both the hypomorph character of the mutations and hyperactivation of the RNAi pathway, which is known to regulate telomere function (Ho et al. 2008). Consistent with this hypothesis, the frequency of telomere fusions is also low in *woc^{RNAi}*. The contribution of ROW to telomere function was also analyzed in *row^{l(2)SH2172}*, which corresponds to a very strong mutation caused by a P-element insertion at the ATG-start codon (Supplemental Fig. S1B). The incidence of telomere fusions is significantly higher in homozygous *row^{l(2)SH2172}* flies than in control wild-type flies (Supplemental Fig. S5), confirming its contribution to telomere function. The use of currently unavailable *hp1c*-null mutations is also likely to confirm the contribution of HP1c to telomere function.

HP1a is also known to regulate telomere function (Fanti et al. 1998). Several observations, however, indicate that the contribution of WOC/ROW/HP1c is not related to that of HP1a. On one hand, *su(var)2-5* mutants show much stronger effects than either *woc* or *row* mutants (Fanti et al. 1998; Raffa et al. 2005). Furthermore, both telomere length and expression of the telomeric retrotransposons *Het-A* and *TART* are increased in *su-*

(*var*)2-5 mutants, but they are not affected in *woc*-null mutants (Perrini et al. 2004; Raffa et al. 2005). In addition, expression profiling data show that, in *hp1c^{RNAi}*, *woc^{RNAi}*, and *row^{RNAi}* mutants, expression of *Het-A* and *TART* is not significantly affected (data not shown). Similarly, other genes known to contribute to telomere function do not change expression in *hp1c^{RNAi}*, *woc^{RNAi}*, and *row^{RNAi}* mutants (data not shown). Altogether, these observations suggest that the contribution of WOC/ROW/HP1c to the regulation of telomere function is direct and independent of their contribution to the regulation of gene expression.

Materials and methods

For a detailed description of the Materials and Methods, see the Supplemental Material.

Fly stocks and antibodies

woc^{RNAi}, *row^{RNAi}*, and *hp1a^{RNAi}* were obtained from VDRC. *row^{l(2)SH2172}* was obtained from Szeged *Drosophila* Stock Center. *hp1c^{RNAi}* transgenic flies were generated according to standard procedures. For targeting experiments, HP1a, HP1b, and HP1c were fused at C terminus to the lacI-DNA-binding domain.

α HP1a, α HP1b, α HP1c, and α ROW antibodies were rat polyclonal. Rabbit polyclonal α WOC antibodies are described by Raffa et al. (2005). Antibodies against histone modifications and RNAPol II forms were commercial (Abcam, Upstate Biotechnologies).

Immunostaining experiments and analysis of telomere fusions.

Immunostaining experiments were performed in S2 cells and polytene chromosomes and imaginal wing discs from third instar larvae, according to standard procedures (see the Supplemental Material). Telomere fusions were analyzed in brain squashes from third instar larvae. Samples were visualized on a Nikon Eclipse E-800 inverted microscope with a Colorview 12 camera or in a confocal Leica TCS SP2-AOBS microscope.

Purification and characterization of multiprotein complexes containing HP1c

Purification of multiprotein complexes was performed from stable S2 lines expressing TAP-HP1c. LC/MS analysis was performed in the Proteomics Unit of the "Institut de Recerca de la Vall d'Hebrón" (Barcelona).

Coimmunoprecipitation experiments

Coimmunoprecipitation experiments were performed with crude S2 nuclear extracts by the addition of α WOC, α DDP1, or no antibodies, according to standard procedures.

Analysis of the interaction of HP1c with H3K9me2,3 in vitro

Analysis of the interaction of HP1c with H3K9me2,3 in vitro was performed with recombinant GST- and His-tagged proteins. Mononucleosomes and total endogenous histones were obtained from S2 cells. GST-pull-down assays and Far-Western analysis were performed according to standard procedures.

Expression profiling analysis

For expression profiling, *Drosophila* Genome 2.0 GeneChip (Affymetrix) were hybridized with cDNA prepared from total RNA obtained from male larvae. Duplicates were processed for each of the genotypes analyzed. For each mutant condition, differential expression was measured via the distance between the intervals containing the mutant and the control expression values. Lists of differentially expressed genes were obtained by setting several cut-offs for the absolute value of the interval distance. To measure the degree of coregulation between the mutants, we computed the pairwise Spearman's rank correlation between interval distances. GO analysis was performed with GToolBox.

Acknowledgments

We are grateful to C. Antoniewski, J. Bernués, M. Batllé, M.L. Espinàs, M. Gatti, A. Jordan, K. Furukubo-Tokunaga, J.T. Lis, A. Veraksa, and L. Wallrath for materials, and to A. Casali, D. Huertas, and I. Garcia-Bassets for helpful advice and discussions. We are most thankful to M. Lloret-Llinares for preliminary studies on the effect of *hp1c^{RNAi}* on gene expression. We are also thankful to E. Fuentes and L. Bardia for technical assistance. J.F. acknowledges receipt of a doctoral fellowship from MEC. This work was financed by grants from MEC (BMC2006-1627, CSD2006-00049) and the CIRIT (2001SGR00344).
