Nearby inverted repeats fuse to generate acentric and dicentric palindromic chromosomes by a replication template exchange mechanism

Gene amplification plays important roles in the progression of cancer and contributes to acquired drug resistance during treatment. Amplification can initiate via dicentric palindromic chromosome production and subsequent breakage–fusion–bridge cycles. Here we show that, in fission yeast, acentric and dicentric palindromic chromosomes form by homologous recombination protein-dependent fusion of nearby inverted repeats, and that these fusions occur frequently when replication forks arrest within the inverted repeats. Genetic and molecular analyses suggest that these acentric and dicentric palindromic chromosomes arise not by previously described mechanisms, but by a replication template exchange mechanism that does not involve a DNA double-strand break. We thus propose an alternative mechanism for the generation of palindromic chromosomes dependent on replication fork arrest at closely spaced inverted repeats.

Oncogene amplification is often an early event in cancer development, providing a proliferative advantage for clonal expansion (Slamon et al. 1987; Futreal et al. 2004), while the amplification of genes involved in drug metabolism is a common mechanism by which tumor cells acquire chemotherapy resistance (Gorre et al. 2001). Models for the mechanism of gene amplification implicate the initial formation of a dicentric chromosome that subsequently undergoes repeated breakage–fusion–bridge (BFB) cycles. Following multiple BFB events, dicentric chromosomes can ultimately be stabilized by telomere addition at break sites to form monocentric chromosomes containing megabase-sized palindromic regions. These regions are proposed to form a platform for subsequent gene amplification (segmental amplification) by aberrant recombination or replication (McClintock 1941; Lobachev et al. 2002; Debatisse and Malfor 2005; Rattray et al. 2005; Tanaka et al. 2005; Watanabe and Horiuchi 2005). Acentric palindromic chromosomes have been proposed to be precursors for extrachromosomal elements, including “double minutes,” and, at least in yeast

models, can accumulate in response to selection for gene amplification (Albrecht et al. 2000; Narayanan et al. 2006).

The initial formation of dicentric chromosomes that precede BFB cycles has proved hard to directly visualize, and thus the mechanisms that have been proposed for their formation are based on the analysis of the structures of their stabilized products (Chen and Kolodner 1999; Pennaneach and Kolodner 2004; Haber and Debatisse 2006; Lewis and Cote 2006; Lobachev et al. 2007). Current models for palindromic chromosome formation fall into three categories. In the first (Fig. 1A), palindromic chromosomes are produced following either a double-strand break (DSB) or telomere attrition in G1 phase of the cell cycle. Following DNA replication, two identical broken sisters are produced in G2 phase. Direct ligation of the two intersister uncapped DNA ends—for example, by nonhomologous end-joining (NHEJ) (Pennaneach and Kolodner 2004)—produces a palindromic dicentric or acentric chromosome. This mechanism should require Ku70 and Lig4, proteins essential for NHEJ. In the second category, a single DSB occurs close to a small inverted repeat (Fig. 1B). Following processing to generate a short region of ssDNA, repeat-mediated intrastrand annealing and subsequent ligation form a chromosomal fragment with one hairpin-capped end. DNA replication will

Figure 1. Generation of palindromic chromosomes. (A) An uncapped end is generated by a DSB (or by telomere attrition, not shown). The resulting molecule is then replicated, producing two identical uncapped sister chromatids. The two free ends are directly ligated (for example, by NHEJ), and this results in a palindromic dicentric or acentric palindrome. Open circles indicate centromeres, zig-zag lines represent telomeres, and single lines indicate ssDNA. (B) An uncapped end near a short inverted repeat (in red) can, after processing to reveal ssDNA, result in a “snap-back” strand annealing between the inverted repeats, generating a hairpin at the chromosome end. Following fill-in and ligation, this will generate a capped end that resolves into a giant palindrome after DNA replication. (C) If the palindrome extrudes, it will generate a cruciform structure. This resembles an HJ, has hairpin ends, and can be processed by a structure-specific nuclease such as Mus81 (right) or by the MRN complex (left). (Left) If both hairpins are cleaved at the apex by MRN, this results in a break at the

center of the palindrome. This can subsequently be repaired by end-joining. This process can result in gain or loss of sequences at the center of the palindrome (blue), and ultimately result in its stabilization or complete loss. If the extrusion is cleaved by HJ resolvase, it is able to form hairpin-capped chromosomes by ligation. Following DNA replication, these can result in acentric and dicentric giant palindromes. This process is suppressed by MRN activity, which can open the hairpin at the chromosome end, thus generating an uncapped end, a substrate for schematic A.

resolve this structure into a giant palindromic chromosome, unless the hairpin is first cleaved by an endonuclease such as those associated with the Mre11/Rad50/Nbs1 (MRN) complex. This mechanism should involve specific nucleases and proteins involved in single-strand annealing and be independent of homologous recombination (HR). In the third model, relevant only to palindromic sequences, the hairpin extrudes and is then broken at one of two sites (Fig. 1C): If a nuclease (i.e., MRN) nicks both of the extruded hairpin ends simultaneously (Fig. 1C, left), this causes a DSB that, following processing and end-joining, can result in reformation of the chromosome (often associated with loss or gain of sequences at the palindrome center). Alternatively, the extruded palindrome, which resembles a Holliday Junction (HJ), can be cleaved centrally by structure-specific nucleases. The consequence of this is the formation of a hairpin-capped chromosome end (Fig. 1C, right). As for model B, DNA replication can resolve this into a palindromic chromosome. This mechanism should involve Holliday structure nucleases, depend on the ability of the palindrome to extrude, and be independent of HR.

The early stages of carcinogenesis are proposed to be associated with oncogene-mediated replication-dependent genomic instability (Bartkova et al. 2005; Gorgoulis et al. 2005), and proliferating tumor cells exhibit genetic instability associated with deregulated replication (Vogelstein and Kinzler 2004; Aguilera and Gomez-Gonzalez 2008). Thus, we set out to test how replication fork arrest influences the formation of dicentric and acentric palindromic chromosomes. Using a series of inverted repeat and palindromic loci in fission yeast, we find that nearby inverted repeats can fuse to form acentric and dicentric

chromosomes, that they do so at high frequency when DNA replication is arrested within the repeats, that the majority of events are HR protein-dependent, and that these chromosomal rearrangements occur independently of a DSB intermediate. Our analysis leads us to propose a new replication template exchange (RTE) model for palindromic chromosome formation.

Results

We demonstrated previously that replication fork arrest leads to increased recombination and gross chromosomal rearrangements (GCRs). The experimental system used (RuraR) (see Fig. 2A) consisted of two 859-base-pair (bp) replication termination sequences (RTS1) introduced at the *ura4⁺* locus as inverted repeats flanking 1.7 kb of nonrepetitive DNA (Lambert et al. 2005). In RuraR, the RTS1 sequences serve two functions: They are inverted repeats that can recombine to fuse with each other, and they provide the means to conditionally and efficiently stall replication forks. To probe the effect of fork arrest within a small perfect or imperfect palindrome, we modified the locus to create a related series of constructs (Fig. 2A). These include (1) a perfect 5.3-kb palindrome that contains the inverted replication arrest sites as its terminal sequences, with two *ura4* sequences in inverted orientation [RuuR]; (2) a similar construct in which the palindrome center is interrupted by a 14-bp “spacer” [RuiR]; (3) a series of constructs to examine repeat orientation and size [Ru(dir)uR] plus transcriptional orientation and size [RuhR]; and (4) a construct to examine the orientation of the replication fork barriers [oRuiRo].

Figure 2. Replication fork arrest within a palindrome causes the formation of acentric and dicentric chromosomes. (A) Schematic of the constructs integrated at the *ura4* locus on ChrIII. (Blue) RTS1; polar RTS1. The bar in RTS1 indicates the direction that, when a fork approaches, it will be arrested. Red arrows below the *ura4* (yellow) and *his3* (green) sequences indicate the direction of transcription. Boxes Cen and Tel indicate position of probes used. Ovals show the *ars* sequences. (Inset) Schematic of acentric and dicentric chromosomes. The 14-bp insertion interrupts the symmetry of the palindrome center in RuiiR and oRuiiRo. (B) Viability analysis of perfect (RuuR) and interrupted (RuiiR) palindrome strains in the presence (pause on; +, *rtf1*⁺) and absence (pause off; –, *rtf1*⁺ or *rtf1*-d) of fork arrest. Note that loss of viability is dependent on fork arrest by *rtf1*⁺ induction. (C) Representative images of RuiiR mitotic catastrophe 24 h after thiamine removal (approximately three generations of growth under conditions in which forks arrest at RTS1). DNA stained with DAPI, and septum stained with Calcofluor. (D) PFGE and Southern blot analysis of strains either unable to arrest forks at RTS1 (*rtf1*Δ) or where *rtf1* is regulated by thiamine ([–] low transcript and

minimal arrest; [+], high transcript and efficient fork arrest). Note that formation of 1.4-Mb DNA is correlated with loss of viability in B. (E) PFGE and Southern blot analysis of cells without fork arrest (off; –) and 24 h after (on; +) arrest is induced. (Left panel) Ethidium bromide staining. (Middle panel) Telomere-proximal probe. (Right panel) Centromere-proximal probe. I, II and III indicate fission yeast chromosomes. Arrows: 3.5 Mb, ChrIII; 1.4 Mb, acentric; 5.6 Mb, dicentric. (*) Smear corresponding to breakage.

Fork arrest at RTS1 has been extensively characterized; it is direction-dependent and requires the Rtf1 protein (Codlin and Dalgaard 2003; Eydmann et al. 2008). In the absence of the *rtf1*⁺ gene, we and others have demonstrated that replication forks no longer arrest at RTS1 and that this sequence is replicated normally (Lambert et al. 2005). To regulate fork arrest, we thus used an attenuated thiamine-repressible promoter (*nmt41*) to regulate *rtf1*⁺ transcription at its own locus (*nmt:rtf1*⁺). Because repression is somewhat leaky, we also used an *rtf1*-null (*rtf1*-d) mutant background to entirely eliminate programmed fork arrest at RTS1. In the presence of induced Rtf1 protein, >95% of the forks arrest at the RTS1 (Supplemental Fig. S1; data not shown), and HR protein-dependent mechanisms are required to process them to restart replication (Lambert et al. 2005).

Fork arrest within a palindrome causes a high frequency of chromosomal rearrangement

RuuR cells (harboring the perfect small palindrome) and RuiiR cells (interrupted small palindrome), respectively, exhibit either modest or no viability loss in the absence of Rtf1 (compared with a control strain not harboring the construct) (Fig. 2B; data not shown). When *rtf1*⁺ is induced (*nmt:rtf1* without thiamine) to switch on fork arrest, both RuuR and RuiiR cells showed significant viability loss (Fig. 2B; Supplemental Fig. S2). This inviability correlated with the appearance of a mitotic catastrophe phenotype in ~20%–25% of cells (Fig. 2C), and the production of

a 1.4-Mb acentric giant palindromic chromosome (pulse field gel [PFG] analysis) (Fig. 2D). Restriction fragment analysis by Southern blot demonstrated that DNA fragments consistent with both acentric and dicentric chromosomes are rapidly produced at approximately equal frequency (Supplemental Fig. S3). When transcription is repressed (*nmt:rtf1*⁺ with thiamine), low levels of rearrangement are observed in both RuuR and RuiiR cells (Fig. 2D). However, when the *rtf1*⁺ gene is deleted (*rtf1*-d), this low level of rearrangement is not seen for the interrupted palindrome construct (RuiiR), but remains detectable for the perfect palindrome (RuuR) (Fig. 2D). Thus, the GCRs visible in RuiiR cells are *rtf1*⁺-dependent and are induced by replication fork arrest. The RuuR construct is somewhat unstable even in the absence of *rtf1*⁺ and replication fork arrest. We infer that the perfect palindrome forms rearrangements due to spontaneous cruciform extrusion, and that this is prevented by stabilizing the palindrome center with a 14-bp insertion. We thus concentrated further analysis on the interrupted palindrome (RuiiR) system, where rearrangement is dependent on replication fork arrest.

We next evaluated the percentage of chromosomal rearrangements. We can visualize four molecular species that help answer this question: First, probing a PFG with a centromere-proximal probe visualizes a faint 5.6-Mb band (Fig. 2E), corresponding to the size of the dicentric chromosome (Fig. 2A, inset) and predicted from restriction enzyme analysis (Supplemental Fig. S3). Second, a smear of smaller fragments suggests random breakage of

the dicentric chromosome during mitosis. This is consistent with the visualization of DAPI-staining material stretched between two nuclei following mitosis (Fig. 2C). Third, we can visualize the acentric chromosome formed, and fourth, we can visualize the original chromosome III (ChrIII).

When arrest is induced, there is an increase in all three species indicative of the acentric and dicentric palindromic chromosome formation (1.4- and 5.6-Mb chromosomes and a smear of small fragments). The majority of the 3.5-Mb ChrIII band is also absent from PFGEs (see Figs. 2, 3; Supplemental Fig. S4). It is likely that ChrIII does not enter the gel efficiently when replication is stalled and restarted by HR protein-dependent mechanisms, because joint molecules that are produced as intermediates during restart by HR proteins accumulate (Supplemental Fig. S1). Unfortunately, under the PFGE electrophoresis (PFGE) conditions used to resolve fission yeast chromosomes, it is not possible to quantify the DNA remaining in the wells. We interpret the dramatic loss of ChrIII as a combination of two events: First, a percentage of the chromosomes undergo GCRs to form acentric and dicentric products. Second, the remaining chromosomes, while ultimately completing replication following fork restart,

are, for a significant time, in possession of replication and joint molecule intermediates that preclude PFGE entry. This is consistent with our demonstration that RTS1 sites integrated at this locus arrest the majority of replication forks (Supplemental Fig. S1; Lambert et al. 2005), which are subsequently restarted by HR protein-dependent mechanisms.

Acentric palindromic chromosomes are also generated from nearby inverted repeats

Near-perfect palindromes are uncommon in the human genome (Bailey et al. 2002). More common are repeated sequences such as *Alu* elements that are usually separated by other sequences. Interestingly, very closely spaced inverted *Alu* repeats and *Alu* palindromes are significantly underrepresented (Lobachev et al. 2000; Stenger et al. 2001), suggesting specific evolutionary pressure against such arrangements. To establish if our model system has relevance to spontaneous genomic rearrangements at endogenous inverted repeat structures, we examined if acentric chromosomal palindromes could occur as a consequence of replication fork stalling within nearby inverted repeats.

Figure 3. Fork arrest at inverted repeats also results in large palindromic chromosomes. (A) PFGE of DNA from the indicated strains either without (off; -) or 48 h after (on; +) the induction of *rtf1*-dependent fork arrest. (Left) Ethidium stained. (Right) Southern blotted with a telomere-proximal probe. The percentage of signal corresponding to the acentric chromosome (1.4 Mb) was calculated (numerals) as a percentage of total signal ($2 \times 3.5 \text{ Mb} + 1.4 \text{ Mb}$). (B, left) Schematic. (Blue) RTS1. (Bar in RTS1) The direction that, when a fork approaches, it will be arrested. Red arrows below *ura4* (yellow) and *his3* (green) indicate direction of transcription. (Solid triangle) 14-bp "interruption". (Right) Viability analysis in the absence (Pause on) or presence (Pause off) of thiamine to regulate *rtf1* for the strains indicated. (C) Schematic of the expected pattern of replication arrest for RuiuR and oRuiuRo. The blue bar indicates the direction that, when a fork approaches, it will be arrested.

First, we studied rearrangements in the original RuraR construct (859-bp repeats separated by 1.7 kb), as well as additional constructs that contain nonpalindromic sequences between the RTS1 inverted repeats (see Fig. 2A). We found that all constructs containing RTS1 inverted repeats flanking unique sequences generated acentric (Fig. 3A) and dicentric chromosomes (data not shown) when replication forks are arrested in the repeats. Thus, these constructs undergo inverted repeat fusion, but at a >10-fold lower frequency than seen for RuiuR. Consistent with this, they do not significantly lose viability upon induction of fork arrest (Fig. 3B, right). We also included a construct (oRuiuRo) in which the orientation of the RTS1 polar replication fork barrier was inverted compared with RuiuR. The significance of this construct is that forks must pass through the palindrome before being arrested (Fig. 3C), making arrest possible at only one site in any one S phase. The oRuiuRo construct forms detectable levels of the acentric chromosome upon fork arrest. Thus, a single arrested fork within an interrupted small palindrome (oRuiuRo) can precipitate the production of palindromic chromosomes.

Genetic test for the mechanism of acentric palindrome chromosome formation

We next tested various models for palindromic chromosome formation. To review, each of the three mechanisms presented in Figure 1 makes concrete genetic predictions (Butler et al. 2002; Cote and Lewis 2008). For model A, where chromosomes break, replicate, and then fuse, NHEJ would be required. For model B (intramolecular annealing), structure-specific nucleases Rad32^{Mre11} (MRN) and Rad16^{Rad1}-Swi10^{Rad10} are implicated, and there is no expected dependence on the strand invasion HR protein Rhp51^{Rad51}. Model C (cruciform cleavage) implicates HJ nucleases Slx1/4 and Mus81 and also predicts independence from strand invasion protein Rhp51^{Rad51}. Lastly, a chromosome break within the repeat followed by break-induced replication (BIR) would implicate the full range of HR proteins (Llorente et al. 2008).

We thus analyzed cell viability and the production of the acentric chromosome in a variety of genetic backgrounds. Loss of the Pku70, Lig4, Slx1, Rad32^{Mre11}, or Swi10^{Rad1}/Rad16^{Rad10} nucleases did not reduce acentric formation (Fig. 4A; Supplemental Fig. S5A,C,E,F). Loss of Mus81 slightly increased rearrangement (Fig. 4A). From this we conclude that the main mechanism producing the acentric and dicentric chromosomes is not chromosome fusion (NHEJ-dependent), intramolecular strand annealing, or cleavage of cruciform extrusion (MRN, Swi10^{Rad1}/Rad16^{Rad10}, or Slx1/4, Mus81-dependent).

We next analyzed the role of HR proteins (Fig. 4B). Upon expression of *rtf1*⁺ (no thiamine), loss of core HR proteins Rhp51^{Rad51}, Rhp54^{Rad54}, or Rad22^{Rad52} decreased acentric formation ~90% when compared with *rad*⁺ cells. This supports the elimination of models for intramolecular strand annealing and cleavage of cruciform extrusion (which should be independent of strand invasion). Cell death in HR mutant backgrounds, when

Figure 4. HR proteins are required for viability and GCR. (A,B) DNA prepared from RuiuR strains indicated, grown either without (off; -) or three generations after (on; +) the induction of *rtf1*-dependent fork arrest, was analyzed by either PFGE (left) or SalI digestion (right) (see Supplemental Fig. S3C for SalI fragments) and Southern blotting with a telomere-proximal probe. The panel labeled “rad60” represents the same gel probed with a ChrIII-specific probe. (Bottom) The ratio of signal corresponding to the acentric chromosome (1.4 Mb or 10.3 kb, respectively), expressed as a percentage) was calculated compared with total signal ($2 \times 3.5 \text{ Mb} + 1.4 \text{ Mb}$ or $2 \times 19.8 \text{ kb} + 10.3 \text{ kb}$). The *rad22Δ rhp51Δ* strain was used because *rad22^{rad52}* mutants can accumulate suppressors that are Rhp51^{Rad51}-dependent. *rad32 = mre11*. (C) Viability analysis in the presence (Pause off) or absence (Pause on) of thiamine to regulate *rtf1*.

compared with *rad*⁺ cells, was greatly increased (Fig. 4C). Our previous data supported the notion that, following replication fork arrest at RTS1, HR proteins are required for replication restart. Thus, we propose three fates for a stalled fork: The first is replication resumption via an HR protein-dependent mechanism that leads to an unaltered ChrIII. Cells undergoing this event are viable (Lambert et al. 2005). A second fate is to restart replication at the expense of recombination protein-dependent fusion between repeats to form acentric and dicentric chromosomes. These cells are inviable. The third fate is failure to resume replication. Such cells do not undergo subsequent

repeat fusion, but are inviable due to incomplete replication. *rad*⁺ cells usually resume or resume and fuse their repeats (fates one and two), while HR mutants generally fail to resume and thus also fail to form repeat fusions.

In the MRN mutant backgrounds, we observe an increase in the level of rearrangements upon quantification of both PFGE and restriction fragment analysis (Fig. 4A). This is combined with viability loss (Fig. 4C; Supplemental Fig. S2). This indicates that recombination protein-dependent processing of the stalled fork does occur in these cells, but that it may be inappropriately channeled into lethal events, some of which result in giant palindromic chromosome formation. Alternatively, the accumulation of palindromic chromosomes in MRN mutants could reflect a combination of two effects: a loss of the predominant HR protein-dependent mechanism of fork restart (and thus of palindrome formation), combined with the loss of a usually cryptic role for Rad32^{Mre11} nuclease activity in suppressing alternative pathways (i.e., Fig. 1C, right) that lead to an equivalent rearrangement via mechanisms that rely on the generation of hairpin ends (Lobachev et al. 2002). Mre11 is proposed to efficiently cleave such structures.

Evidence for a lack of DSBs associated with the rearrangement

Current models for replication fork restart, derived largely from *Escherichia coli*, invoke a one-ended DSB that recruits HR to invade the partially replicated sister chromosome to reinitiate replication (Haber and Heyer 2001). Such a BIR model would explain both the requirement for HR proteins for cell viability (correct fork restart) and our genetic data for palindromic chromosome formation (incorrect invasion of the twin repeat resulting in BIR replicating to the chromosome end). To test for DSBs associated with replication fork restart, we took two approaches: First, we used both the RuiuR and the RuraR constructs to look for evidence of DSBs by PFGE and restriction fragment analysis. Second, we used synchronized RuraR cells to look for DSBs within a single cell cycle. We reasoned that, if replication fork restart initiates via BIR, the majority of chromosomes in our cultures must be transiently broken and exhibit a polar DSB (the majority of forks arrest at the RTS1 sequences) (Supplemental Fig. S1; Lambert et al. 2005), and recombination proteins will be required for their restart (Fig. 4; Lambert et al. 2005). A chromosomal fragment with a polar DSB will first be processed by MRN-dependent nuclease, bound by Rad51 filament, and subsequently initiate invasion of the partially replicated sister chromosome. Thus, to eliminate the possibility that we could fail to detect DSBs due to rapid processing and/or the initiation of recombination, we also analyzed strains in which MRN was defective (delayed processing) and/or strand invasion was prevented (Rad22^{Rad52} or Rhp51^{Rad51} absent).

In our first approach, we examined both RuiuR and RuraR in repair-competent (*rad*⁺) and HR processing and repair-deficient backgrounds by PFGE and restriction fragment analysis (Fig. 5). A polar DSB caused by replica-

tion arrest in either RuiuR or RuraR would be detected as a centromere-proximal fragment of 2.8 Mb on PFGEs probed with sequences corresponding to the right arm of ChrIII. If first cleaved by the rare cutter *AscI*, this would reduce the fragment size to ~650 kb when combined with a polar break at RuiuR (Fig. 5A). However, analysis of native and *AscI* cleaved samples did not reveal a band diagnostic of a DSB at RuiuR (Fig. 5B). Similarly, we could find no evidence for a significant fraction of DSBs associated with forks arrested at RTS1 in RuraR backgrounds (Fig. 5D). Consistent with these PFG analyses, we did not detect DSBs upon fork arrest by restriction fragment analysis in either the RuraR (Fig. 5C) or RuiuR (data not shown) backgrounds.

In the second approach, we sought to detect DSBs when a culture harboring RuraR was synchronized in G2 and released into a synchronous S phase following induction of *nmt:rtf1* to switch on fork arrest (Fig. 6). We induced *rtf1*⁺, synchronized cells in G2 phase with a *cdc25-22* temperature-sensitive mutant at 36°C, and released cells into the next cell cycle by temperature shift-down. FACS analysis showed that bulk replication occurs at ~90 min and is complete by ~150 min after release from the *cdc25* block (Fig. 6A). Two-dimensional gel electrophoresis demonstrated the efficiency of replication arrest and its dependence on Rtf1 (Fig. 6B). As in our previous work (Lambert et al. 2005), in the presence of fork arrest we could not detect Y molecules that would correspond to normal replication fork progression through the locus because most forks are arrested at the RTS1. Southern analysis of *AseI*-digested DNA (Fig. 6C) showed that >25% of the DNA is present in a high-molecular-weight smear that peaked during S phase (Fig. 6D). This likely represents the replication and/or recombination protein-dependent intermediates visualized in Figure 6B. We could not detect evidence for an S-phase-specific DSB at the RTS1 site. Taken together, these experiments provide strong evidence that replication restart by recombination protein-dependent mechanisms in this system is not associated with DSBs at the site of fork arrest, and is thus independent of BIR.

Discussion

Palindromes are thought to be underrepresented in the genome because they are intrinsically unstable and can be eliminated by a variety of processes in both meiosis (Nasar et al. 2000; Farah et al. 2005) and mitosis (Lewis and Cote 2006; Lobachev et al. 2007). Closely spaced inverted repeats with <20 bp of separation are also underrepresented, likely due to evolutionary counterselection. Even when repeat homology is as low as 86%, such closely spaced inverted repeats can underlie the generation of palindromic chromosomes (Lobachev et al. 2000). Here we report a model system that helps to explain why these two classes of repeat geometries are underrepresented: They can form acentric and dicentric palindromic chromosomes when replication forks stall within them. We show that recombination proteins are required for the majority of these GCRs, and that the inverted repeats can

Figure 5. Fork arrest at RuiuR or RuraR results in chromosomal rearrangement without DSB formation in *rad*⁺ cells and in processing (*rad50*) and recombination (*rad22*^{rad52}) of defective mutants. (A) Schematic of the RuiuR or RuraR constructs integrated at the *ura4* locus of ChrIII. The bar in RTS1 indicates the direction that, when a fork approaches, it will be arrested. Boxes *ade6* and *rng3*, the bar *cen*, and the circle *cent3* indicate the positions of probes. Note that ARS3004 and ARS3005 are efficient ARSs. The single *Ascl* site is indicated. (B, left) Southern hybridization of a PFG using a centromere-proximal probe either without the induction of *rtf1*-dependent replication fork arrest (pause –) or 48 h after the induction (pause +) in the indicated RuiuR strains. If a DSB occurred at RuiuR, a 2.8-Mb band would represent a fragment derived from the DSB to the right telomere. This was not seen; the expected position is indicated by a red bar. (Right) *Ascl*-digested DNA was analyzed by PFGE and Southern blotting with a centromere-proximal probe. The *Ascl* site is a unique site on *S. pombe* ChrIII and would generate a 650-kb fragment if combined with a DSB at RuiuR. No such signal is seen; compare tracks 3 and 4. The expected position is indicated by a red bar. (C) Southern blot analysis of *AvaI* restriction fragment derived from indicated RuraR strains without (–) and 24 h after (+) arrest is induced. Asterisk (*) represents a nonspecific band. Below is a schematic of the *RuraR* construct digested by the restriction enzyme *AvaI*. A polar DSB would result in the generation of a 2.2-kb

fragment revealed with the Cen probe. This was not seen; the expected position is indicated by a red bar. (D, left) A PFG of chromosomes from the indicated RuraR strains stained with ethidium bromide or probed with indicated probes. (–) Pause off; (+) pause on for 24 h. Positions of *H. wingei* chromosomes are indicated as size markers. The bold arrow indicates the position of the acentric chromosome at 1.4 Mb. The predicted fragment in the case of a DSB at RuraR is 0.7 Mb for the *Rng3* probe. The *ade6* and *cent3* probes would show a 2.8-Mb fragment in the case of a DSB. These were not detected; the expected positions are indicated on the right by a red bar. In the absence of both Rad50 and Rad22^{Rad52} (DSB resection and HR), a smear above 2.8 Mb is evident. However, this appeared whatever ChrIII probe was used, which thus does not reflect a specific polar DSB, but likely reflects fragmentation of the chromosome.

fuse by a mechanism that does not appear to involve a DNA DSB and is thus independent of BIR.

Replication restart and chromosome rearrangements can occur independently of DSBs

Fork arrest occurs at ~95% of RTS1 sequences when fork stalling is induced in our systems in either *rad*⁺ or HR mutant backgrounds (see Fig. 6B; Supplemental Fig. S1; data not shown). Resumption of replication requires HR proteins, and this is reflected in a dramatic loss of viability for RuiuR cells in an HR mutant background when fork arrest is induced (Fig. 4C; Supplemental Fig. S2). In *rad*⁺ HR-proficient cells, fork restart at RuiuR occurs at the expense of a high level of chromosome rearrangement into acentric and dicentric chromosomes, which itself causes significant viability loss due to an inability to segregate chromosomes. Analysis of the accumulation of these acentric and dicentric chromosomes demonstrates that an HR protein-dependent mechanism underlies their production. Despite the highly efficient fork arrest and the fact that recombination proteins are required for fork restart, we were unable to

detect DSBs associated with fork arrest in synchronized cell populations or in genetic backgrounds deficient in either DNA processing (MRN complex mutants) or strand invasion (HR mutants). Even in the *rad50-d rad22-d*^{rad52} double mutant background (absence of both processing and strand invasion) (Fig. 5), no DSBs were observed. These data provide a compelling indication that the major mechanism(s) of fork restart and subsequent chromosomal rearrangement in this model system do not proceed via a DSB intermediate and are thus distinct from BIR.

RTS1 is a protein-dependent programmed fork barrier. GCRs, however, are generally associated with stochastic fork stalling. In the absence of programmed fork stalling (*rtf1* deletion), we find that the RuiuR locus can generate rearrangements equivalent to Rtf1-dependent GCRs in response to MMS treatment (Supplemental Fig. S6). Thus, while we do not propose that the RTS1/Rtf1 fork arrest-dependent palindromic chromosome formation we visualize here exclusively represents how such deleterious structures arise in response to replication problems, we propose that it provides a relevant model for the generation of rearrangements that are not initiated by DSBs

Figure 6. Absence of a detectable DSB induction in synchronized cells. RuraR *rtf1*⁺ and RuraR *rtf1-d* cells were grown without thiamine (14 h) and were synchronized by *cdc25.22* block and release. The time course starts after cell cycle release. Asynchronous cultures were grown for 24 h with (–; pause off) and without (+; pause on) thiamine as a control where appropriate. (A) FACS analysis. The culture before the cell cycle arrest was used as asynchronous control culture “Async.” S phase occurs between 60 and 150 min. (B) Two-dimensional gel electrophoresis at specified time points with (*rtf1*⁺) and without (*rtf1-d*) fork arrest (a–d as indicated) (see Supplemental Fig. S1). (Bottom) Map of AseI digest for RuraR. The position of the Cen probe is indicated by the bar. In the merged picture, the signal corresponding to 90 min for *rtf1-d* is red and that for *rtf1*⁺ is blue. (C) Southern hybridization of one-dimensional gel to visualize replication intermediates (RI) from the indicated times. DNA was digested with AseI. (D) Quantification of one-dimensional gel showing the percentage total signal present in replication intermediates (red squares) and at the position of a predicted break (blue diamonds). Forks broken within the Cen-proximal RTS1 would generate a band of ~1500 bp. A faint signal between 1.5 and 2.0 kb is seen in the G2-arrested sample (0 min), but this is lost when cells enter S phase (75 min).

when forks are stochastically stalled within short palindromes.

An RTE model for fork restart-associated chromosome rearrangements

In *E. coli*, fork restart by HR commonly proceeds through a polar DSB intermediate (Haber and Heyer 2001). In eukaryotes, it has not been established if DSBs are either a common or essential intermediate during restart (Fabre et al. 2002; Aguilera and Gomez-Gonzalez 2008), but this has often been assumed to be the case. Our analysis demonstrates that fork restart and the subsequent recombination protein-dependent fusion of two inverted repeats that results in palindromic chromosome formation occur independently of a DSB when forks are arrested at RTS1. We also demonstrate that neither the post-replication repair pathway (Supplemental Fig. S5E–G) nor structure-specific nucleases such as Mus81, Mre11, Slx1/4, Rad16^{Rad1}/Swi10^{Rad10}, or Rad2^{Fen1} (Supplemental Fig. S5C,E–G) are required for fork restart (as judged by viability) or for the subsequent generation of palindromic chromosomes. Thus, we propose that HR protein-dependent replication is initiated from a single-stranded gap at a stalled fork, and

that this can result in a template exchange event that results in inappropriate fusion of inverted repeats by a recombination protein-dependent mechanism (Fig. 7). The precise method of such a DSB-independent fork restart process and how it results in the deleterious template exchange remain subjects for future investigation.

There is evidence from several systems (i.e., Zhang and Freudenreich 2007; for review, see Aguilera and Gomez-Gonzalez 2008) that DSBs can be associated with fork arrest-induced GCR in eukaryotes, and we do not argue that DSBs cannot be a consequence of fork arrest or an intermediate in fork restart. Distinct replication fork barriers are likely to result in the production of different DNA and/or DNA–protein structures, and these will, in turn, elicit distinct modes of DNA processing and subsequent repair (Lambert and Carr 2005; Lambert et al. 2007; Aguilera and Gomez-Gonzalez 2008). However, in support of the potential relevance of fork restart independent of a DSB at RTS1, it is of interest to note DSB-independent HR has been proposed previously to occur in budding yeast (Payen et al. 2008) and following blocks to mammalian DNA replication by thymidine, in contrast to hydroxyurea treatment, where HR was seen to be associated with DSBs (Lundin et al. 2002). Furthermore,

Figure 7. An RTE model for giant palindrome formation. After fork arrest, a recombinogenic 3' end is formed by association with HR proteins (yellow). (Left) Recombination protein-dependent fork restart results in reinvasion at the correct locus (i) and completion of replication (ii,iii). (Right, iv) Alternatively, erroneous invasion occurs in the opposite repeat. The dashed line indicates an area synthesised by restart of coupled leading and lagging strand synthesis. Replication subsequently continues around the palindrome (v) and creates an HJ following ligation to the lagging strand of the oncoming fork (vi). HJ resolution in the horizontal plane results in acentric and dicentric chromosome formation. Resolution in the vertical plane results in fully replicated chromosomes in the original conformation (not shown).

a fork stalling and template switching (FoSTeS) mechanism that is potentially independent of DSBs and occurs at sites of microhomology has been proposed to explain noncontiguous DNA sequences associated with non-recurrent complex chromosome rearrangements typical of a number of inherited genomic disorders (Lee et al. 2007; Zhang et al. 2009). Taken together, the available literature and our own analysis strengthen the suggestion that the nature of the replication fork barrier influences the mechanisms by which replication is restarted.

Summary

Giant palindromes are precursors to BFB cycles and gene amplifications that underlie both cancer etiology and the amplification of target genes during acquired resistance to chemotherapy. Our DSB-independent HR protein-dependent RTE model for their generation following replication fork arrest within inverted repeats or small palindromic sequences therefore has significant potential consequences for the understanding of the mechanisms of genomic instability associated with palindromic chromosomes, and may also help explain how chromosome regions with complex architectures and fragile sites capable of forming extensive secondary structures (Durkin and Glover 2007; Zhang and Freudenreich 2007) become

susceptible to increased plasticity during replication and in response to replication perturbation.

Materials and methods

Strains were constructed using standard genetic techniques (Moreno et al. 1991; Bahler et al. 1998). The *Schizosaccharomyces pombe* strains used in this study are listed in Supplemental Table S1. For fluorescence microscopy, cells were stained with DAPI (0.5 $\mu\text{g}/\text{mL}$) and Calcofluor (5 $\mu\text{g}/\text{mL}$) after methanol fixation. The modified *nmt1* promoter (*nmt41*) (Basi et al. 1993) was integrated upstream of the *rtf1* ORF (Lambert et al. 2005). Induction following thiamine removal takes 14–16 h. At 24 h, cultures are in a “steady state” after three to four generations of division in the presence of fork arrest. Where appropriate, 100 U of *AscI* were used to digest DNA in an agarose plug equilibrated with the enzyme buffer recommended by the manufacturer. PFGE was performed as described previously (Lambert et al. 2005). Conditions for *Hansenula wingei* chromosomes were as recommended by the manufacturer (Bio-Rad). Southern blot hybridization was performed using standard procedures. The signals were visualized with a PhosphorImager, and band intensities were quantified with an ImageQuant TL program. The ratio of the acentric palindromic chromosome to total ChrIII signal is indicated as a percentage and was calculated as $100 \times 1.4 \text{ Mb} / (2 \times 3.5 \text{ Mb} + 1.4 \text{ Mb})$ or $100 \times 10.3 \text{ kb} / (2 \times 19.8 \text{ kb} + 10.3 \text{ kb})$. Note the duplication of the probe sequence in the acentric.

Serial dilution assay of cell growth

Cells were grown at 30°C in yeast extract media with supplements and washed with sterile water twice. Cells (1.6×10^6) were inoculated in 10 mL of EMM2 containing supplements with (pause off) or without (pause on) 30 μ M thiamine and grown for 24 h at 30°C. Ten microliters of serial (1:10) dilutions (10^3 – 10^7 cells per milliliter) of the cultures were spotted on yeast nitrogen base agar (YNBA) plates containing supplements either with (pause off) or without (pause on) thiamine. Plates were incubated for 3 d at 30°C. For cell cycle synchronization, strain YKM104 harboring the *cdc25.22* allele was used. Cells were grown in EMM2 medium without thiamine for 16 h at 25°C, incubated for 3.5 h at 36°C to block the cell cycle, and then cooled down to 25°C to release them synchronously into the cell cycle.

Probes

Southern blot hybridization was performed using standard procedures with the following probes: Tel probe: a 296-bp PCR-amplified fragment with DU4-for (5'-GGATTCTAACTATGTC TTTTAGAC-3') and DU4-rev (5'-CTTAAGAAAAAACGTC AAGAAATC-3'); Cen probe: a 410-bp PCR-amplified fragment with L1-1-for (5'-TTTAAATCAAATCTTCCATGCG3') and L1-1-rev (5'-GATGCCAGACCGTAATGACAAAA-3'); Rad60 probe: a 743-bp PCR-amplified fragment with Rad60cd0 (5'-GACAACC TAGATGAAGA-3') and Rad60cd60r (5'-TTAGCTGTTTGGA TTCTCTGT-3'); Ura4 and Rng3 probes: as described previously (Lambert et al. 2005).
